(Received 31 October 2014; published 3 February 2015)

Precision measurements of the Higgs boson properties at the LHC provide relevant constraints on possible weak-scale extensions of the Standard Model (SM). In the context of the minimal supersymmetric Standard Model (MSSM) these constraints seem to suggest that all the additional, non-SM-like Higgs bosons should be heavy, with masses larger than about 400 GeV. This article shows that such results do not hold when the theory approaches the conditions for “alignment independent of decoupling,” where the lightest CP-even Higgs boson has SM-like tree-level couplings to fermions and gauge bosons, independently of the nonstandard Higgs boson masses. The combination of current bounds from direct Higgs boson searches at the LHC, along with the alignment conditions, have a significant impact on the allowed MSSM parameter space yielding light additional Higgs bosons. In particular, after ensuring the correct mass for the lightest CP-even Higgs boson, we find that precision measurements and direct searches are complementary and may soon be able to probe the region of non-SM-like Higgs boson with masses below the top quark pair mass threshold of 350 GeV and low to moderate values of tan β.

I. INTRODUCTION

The recent discovery of a scalar resonance at the LHC, with a mass of about 125 GeV and properties resembling that of the Higgs boson of the Standard Model (SM) [1,2], has revived interest in particle physics models in which a SM-like Higgs boson arises in a natural way. The minimal supersymmetric extension of the SM (MSSM) is an example of such a model [3–6]. The Higgs sector of the MSSM consists of two Higgs doublets with tree-level quartic couplings which are related to the squares of the weak gauge couplings. The tree-level Higgs boson mass spectrum consists of two neutral CP-even Higgs scalars $h$ and $H$ (with $m_h \leq m_H$), a CP-odd scalar $A$, and a charged Higgs pair $H^\pm$. The quartic scalar couplings receive quantum corrections whose leading contributions are proportional to the fourth power of the top-quark Yukawa coupling [7]. For top squark masses below a few TeV, an upper bound on the lightest CP-even Higgs boson mass of about 135 GeV is obtained [8].

The observed Higgs boson mass is comfortably below this predicted upper bound.

For large values of the supersymmetric particle masses, the properties of $h$ are determined by $m_A$ and the third-generation supersymmetric spectrum that governs the size of the quantum corrections to the quartic couplings. When $m_A \gg m_h$, one finds that $m_H \sim m_A \sim m_H^\pm$, with corresponding squared-mass differences of $\mathcal{O}(m_h^2)$. Hence, all nonstandard Higgs bosons are heavy and decouple from the low-energy effective theory at the weak scale, which then naturally consists of the light CP-even Higgs boson $h$, with SM-like couplings, as suggested by current measurements. This is the well-known decoupling limit of the MSSM Higgs sector.

In contrast, for values of $m_A \sim \mathcal{O}(m_h)$, the coupling of $h$ to top-quark pairs tends to be enhanced with respect to the SM value. Since the coupling to bottom quarks controls the width of the Higgs boson, such an enhancement leads to an increase of the Higgs width and therefore a reduction of the branching ratios of the Higgs decay into neutral and charged gauge bosons. Such a reduction can become significant for values of $m_A$ below 300 GeV. Hence, precision studies of the lightest CP-even Higgs boson properties can lead to significant constraints on the allowed parameter space of the theory. The large increase of the...
Higgs boson width may be avoided if the properties of $h$ are SM-like, which can occur either via the decoupling limit [10–12] or the so-called alignment limit [11–14].

The alignment limit arises when one of the CP-even Higgs bosons, when expressed as a linear combination of the real parts of the two neutral Higgs fields, lies in the same direction in the two Higgs doublet field space as the two neutral Higgs vacuum expectation values. This alignment does not in general depend on the masses of the nonstandard Higgs bosons. In the MSSM the alignment limit arises due to an accidental cancellation, i.e. not due to any of the usual symmetries of the MSSM, between tree-level and loop-corrected effects resulting from new structures in the potential that are absent at tree level [14]. However, this cancellation occurs quite generically for some value of the potential that are absent at tree level [14]. How ever, this corrected effects resulting from new structures in the symmetries of the MSSM, between tree-level and loop-an accidental cancellation, i.e. not due to any of the usual Higgs bosons. II. OVERVIEW OF THE MSSM HIGGS SECTOR

A. The 2HDM: Theoretical background

The scalar potential of the most general two Higgs doublet extension of the SM may be written in terms of two Higgs doublet fields, \( \Phi_i (i = 1, 2) \), each carrying the same hypercharge quantum number \( Y_H = \frac{1}{2} \) [19]:

\[
V = m_{11}^2 \Phi_1^+ \Phi_1 + m_{22}^2 \Phi_2^+ \Phi_2 - m_{12}^2 (\Phi_1^+ \Phi_2 + \text{H.c.}) + \frac{1}{2} \lambda_4 (\Phi_1^+ \Phi_1)^2 + \frac{1}{2} \lambda_2 (\Phi_2^+ \Phi_2)^2 + \lambda_3 (\Phi_1^+ \Phi_1)(\Phi_2^+ \Phi_2) + \lambda_4 (\Phi_1^+ \Phi_2)(\Phi_2^+ \Phi_1) + \left\{ \frac{1}{2} \lambda_5 (\Phi_1^+ \Phi_2)^2 + [\lambda_6 (\Phi_1^+ \Phi_1) + \lambda_7 (\Phi_2^+ \Phi_2)](\Phi_1^+ \Phi_2 + \text{H.c.}) \right\},
\]

is the squared-mass of the CP-odd Higgs boson and

\[
L_{11} = \lambda_4 c_\beta^2 + 2 \lambda_6 s_\beta c_\beta + \lambda_3 s_\beta^2,
\]

\[
L_{12} = (\lambda_3 + \lambda_4) s_\beta c_\beta + \lambda_6 c_\beta^2 + \lambda_7 s_\beta^2,
\]

\[
L_{22} = \lambda_2 s_\beta^2 + 2 \lambda_7 s_\beta c_\beta + \lambda_5 c_\beta^2.
\]

Diagonalizing the squared-mass matrix \( M^2 \) given in Eq. (6) yields two CP-even Higgs mass eigenstates \( h \) and \( H \), with squared masses

\[
m_{h,H}^2 = \frac{1}{2} [M_{11}^2 + M_{22}^2 \pm \Delta],
\]

where \( m_h \leq m_H \) and the non-negative quantity \( \Delta \) is defined by

\[
\Delta = \sqrt{(M_{11}^2 - M_{22}^2)^2 + 4(M_{12}^2)^2}.
\]

In particular, \( m_h^2 \leq M_{ii} \leq m_H^2, i = 1, 2 \). We also note that the two equations

\[
\text{Tr} M^2 = m_H^2 + m_h^2, \quad \det M^2 = m_H^2 m_h^2
\]

yield the following result:

\[
|M_{12}^2| = \sqrt{(m_H^2 - M_{11}^2)(M_{11}^2 - m_h^2)} = \sqrt{(M_{22}^2 - m_h^2)(M_{11}^2 - m_h^2)}.
\]

The CP-even Higgs mass-eigenstate fields can be expressed in terms of the neutral scalar fields \( \phi_1^0 \) and \( \phi_2^0 \), defined in Eq. (2):

\[
\begin{pmatrix} H \\ h \end{pmatrix} = \begin{pmatrix} c_\alpha & s_\alpha \\ -s_\alpha & c_\alpha \end{pmatrix} \begin{pmatrix} \phi_1^0 \\ \phi_2^0 \end{pmatrix},
\]

where the mixing angle \( \alpha \) is defined modulo \( \pi \), \( c_\alpha \equiv \cos \alpha \) and \( s_\alpha \equiv \sin \alpha \). It is often convenient to restrict the range of the mixing angle to \( |\alpha| \leq \frac{\pi}{2} \). In this case, \( c_\alpha \) is non-negative and is given by
\[ c_\alpha = \sqrt{\frac{\Delta + M_{11}^2 - M_{22}^2}{2\Delta}}. \]  

(16)

and the sign of \( s_\alpha \) is given by the sign of \( M_{12}^2 \). Explicitly, we have

\[ s_\alpha = \frac{\sqrt{2}M_{12}^2}{\sqrt{\Delta + M_{11}^2 - M_{22}^2}}. \]  

(17)

Using Eqs. (11) and (14), one can derive alternative forms for Eqs. (16) and (17):

\[ c_\alpha = \sqrt{\frac{M_{11}^2 - m_H^2}{m_H^2 - m_h^2}}, \quad s_\alpha = \text{sgn}(M_{12}^2) \sqrt{\frac{m_H^2 - M_{11}^2}{m_H^2 - m_h^2}}. \]  

(18)

For completeness, we also record the squared mass of the charged Higgs boson \( H^\pm \):

\[ m_{H^\pm}^2 = m_A^2 + \frac{1}{2}v^2(\lambda_5 - \lambda_4), \]  

(19)

where \( m_A^2 \) is given by Eq. (7).

The recently discovered Higgs boson exhibits couplings to gauge bosons and fermions that are consistent (within experimental errors) with SM expectations. If the 2HDM is realized in nature, it is tempting to identify the observed Higgs boson with the lightest CP-even scalar \( h \), which is a linear combination of \( \phi_1^0 \) and \( \phi_2^0 \) as indicated in Eq. (15). If \( h \) is SM-like, then it follows that in the \( \phi_1^0 - \phi_2^0 \) field space, \( h \) points roughly in a direction parallel to the direction of the scalar field vacuum expectation values. The implications of this observation will now be examined in more detail.

Since the Higgs couplings to gauge bosons are more accurately measured, we first focus on these. The tree-level coupling of \( h \) to \( VV \) (where \( VV = W^+W^- \) or \( ZZ \)), normalized to the corresponding SM coupling, is given by

\[ g_{hVV} = g_{hVV}^{\text{SM}}s_{\beta - \alpha}. \]  

(20)

Thus, if the \( hVV \) coupling is SM-like, it follows that

\[ V \supset \cdots + \frac{1}{2}Z_1(h_1^+H_1)^2 + \cdots + [Z_5(h_1^+H_2)^2 + Z_6(h_1^+H_1)H_1^+H_2 + \text{H.c.}] + \cdots, \]  

(23)

where \[10,20\]

\[ Z_1 \equiv \lambda_1 c_{\beta}^2 + \lambda_2 s_{\beta}^2 + \frac{1}{2}(\lambda_3 + \lambda_4 + \lambda_5)s_{\beta}^2 + 2s_{2\beta}[c_{\beta}^2\lambda_6 + s_{\beta}^2\lambda_7], \]  

(24)

\[ Z_5 \equiv \frac{1}{4}s_{2\beta}[\lambda_1 + \lambda_2 - 2(\lambda_3 + \lambda_4 + \lambda_5)] + \lambda_5 - s_{2\beta}c_{2\beta}(\lambda_6 - \lambda_7), \]  

(25)

\[ Z_6 \equiv -\frac{1}{2}s_\beta[\lambda_1 c_{\beta}^2 - \lambda_2 s_{\beta}^2 - (\lambda_3 + \lambda_4 + \lambda_5)c_{2\beta}] + c_{\beta}c_{3\beta}\lambda_6 + s_\beta s_{3\beta}\lambda_7. \]  

(26)

where \( c_{\beta - \alpha} \equiv \cos(\beta - \alpha) \) and \( s_{\beta - \alpha} \equiv \sin(\beta - \alpha) \). It is therefore instructive to consider under what conditions Eq. (21) can be achieved.

At this stage, there is nothing that distinguishes the Higgs doublets, since one is free to construct new doublet fields that are linear combinations of \( \Phi_1 \) and \( \Phi_2 \) [20]. Consequently, the parameters \( \alpha \) and \( \beta \) are not physical, although the quantity (\( \beta - \alpha \)) is physical (modulo \( \pi \)) since it is related to an observable coupling. To derive an explicit formula for \( c_{\beta - \alpha} \), it is convenient to define the so-called Higgs basis of scalar doublet fields [21,22]:

\[ H_1 = \left( \begin{array}{c} H_1^+ \\ H_1^0 \end{array} \right) = \frac{v_1\Phi_1 + v_2\Phi_2}{v}, \]  

\[ H_2 = \left( \begin{array}{c} H_2^+ \\ H_2^0 \end{array} \right) = \frac{-v_2\Phi_1 + v_1\Phi_2}{v}, \]  

(22)

so that \( \langle H_1^0 \rangle = v/\sqrt{2} \) and \( \langle H_2^0 \rangle = 0 \). From this one can immediately identify that the scalar doublet \( H_1 \) is the one that will have SM tree-level couplings to all the SM particles. It follows that if one of the \( CP \)-even neutral Higgs mass eigenstates is SM-like, then it must be approximately aligned with the real part of the neutral field \( H_1^0 \).

The scalar potential, when expressed in terms of the doublet fields \( H_1 \) and \( H_2 \), has the same form as Eq. (1), but now with coefficients \( \lambda_i \rightarrow Z_i \). Indeed, one can translate all the formulas obtained previously in the original basis of the scalar fields \{\( \Phi_1 \), \( \Phi_2 \)\} into the Higgs basis by taking \( \beta \rightarrow 0 \) and \( \alpha \rightarrow (\alpha - \beta) \). Hence, in the limit of \( c_{\beta - \alpha} \rightarrow 0 \) we have \( h = [\sqrt{2}\text{Re}(H_1^0) - v] \), which means that \( h \) is aligned with the real part of the neutral component of the Higgs basis field that possesses the nonzero vacuum expectation value. The existence of a neutral scalar mass eigenstate with the properties of the SM Higgs boson is equivalent to demanding that \( c_{\beta - \alpha} = 0 \).

The scalar potential in the Higgs basis is given by
and the shorthand notation $s_{2\beta} \equiv \sin 2\beta$, $c_{2\beta} \equiv \cos 2\beta$, etc., has been employed.

It is straightforward to compute the CP-even Higgs squared-mass matrix in the Higgs basis:

$$\mathcal{M}^2_H = \begin{pmatrix} Z_1 v^2 & Z_6 v^2 \\ Z_6 v^2 & m_A^2 + Z_5 v^2 \end{pmatrix}. \tag{27}$$

The significance of $Z_1$ and $Z_6$ can now be immediately discerned. The upper diagonal element of the squared-mass matrix in the Higgs basis, $\mathcal{M}^2_{H11} = Z_1 v^2$, implies that $m_h^2 \lesssim Z_1 v^2$, whereas the off-diagonal element $\mathcal{M}^2_{H12} = Z_6 v^2$ governs the mixing between the Higgs basis fields $H_1^0$ and $H_2^0$. The presence of this mixing yields a nonalignment of the mass eigenstates $h$ and $H$ from the neutral Higgs basis states $H_1^0$ and $H_2^0$. Moreover, if $|Z_6| \ll 1$, then the mass eigenstate approximately aligned with $\text{Re}(H_1^0)$ behaves like the SM Higgs boson. Alternatively, if $m_A^2 \gg Z_1 v^2$, then $Z_1$ and $Z_6$ can be treated as small perturbations in the diagonalization of the CP-even Higgs squared-mass matrix, and $h$ is again SM-like, since it is approximately aligned with $\text{Re}(H_1^0)$.

The mixing angle in the Higgs basis can be obtained simply by using the relations written down for the original basis of the scalar fields. Translating our previous results into the Higgs basis by taking $\alpha \to \alpha - \beta$, $\mathcal{M}^2_{11} \to Z_1 v^2$ and $\mathcal{M}^2_{12} \to Z_6 v^2$, Eq. (14) implies that

$$|Z_6| v^2 = \sqrt{(Z_1 v^2 - m_h^2)(m_H^2 - Z_1 v^2)}, \tag{28}$$

and Eq. (18) yields

$$c_{\beta - \alpha} = \sqrt{\frac{Z_1 v^2 - m_h^2}{m_H^2 - m_h^2}}, \quad s_{\beta - \alpha} = -\text{sgn}(Z_6) \sqrt{\frac{m_H^2 - Z_1 v^2}{m_H^2 - m_h^2}}, \tag{29}$$

in a convention where $|\beta - \alpha| \leq \frac{1}{2} \pi$. Actually, it is somewhat more convenient to adopt a different sign convention in which $s_{\beta - \alpha}$ is non-negative and the sign of $c_{\beta - \alpha}$ is fixed by $Z_6$, since in this convention the sign of the $hVV$ coupling is the same as in the SM [cf. Eq. (20)]. In particular, if we assume that $0 \leq \beta - \alpha \leq \pi$, then we can use Eqs. (28) and (29) rewrite $c_{\beta - \alpha}$ in the more useful form

$$c_{\beta - \alpha} = \frac{-Z_6 v^2}{\sqrt{(m_H^2 - m_h^2)(m_H^2 - Z_1 v^2)}}. \tag{30}$$

Tree-level unitarity (or perturbativity) constraints yield upper limits on the quartic scalar coupling parameters that are roughly of the form $\lambda_i/(4\pi) \lesssim 1$, with similar limits applying to $Z_1$ and $Z_6$. In light of these constraints, there are two ways to achieve $|c_{\beta - \alpha}| \ll 1$, corresponding to alignment and hence to a SM-like $h$.

First, if $m_H^2 \gg m_h^2$, $Z_1 v^2$, $Z_6 v^2$, then it follows that

$$c_{\beta - \alpha} \sim O\left(\frac{Z_6 v^2}{m_H^2}\right), \quad Z_1 v^2 - m_h^2 \sim O\left(\frac{Z_6 v^2}{m_H^2}\right). \tag{31}$$

This is the well-known decoupling limit [10], in which alignment is achieved when $m_H \gg m_h$. Integrating out the heavy scalars yields an effective theory with one CP-even scalar, $h$, with SM couplings.

In contrast, suppose that $|Z_6| \ll 1$. This is the only case that can result in exact alignment (corresponding to $Z_6 = 0$), and we will henceforth refer to this case as the alignment limit, which exists independently of the decoupling limit. Indeed, Eqs. (28) and (30) imply that if $|Z_6| \ll 1$ and $m_A^2 \gg Z_1 v^2$, then

$$c_{\beta - \alpha} \sim O(Z_6), \quad Z_1 v^2 - m_h^2 \sim O(Z_6^2 v^2), \tag{32}$$

in which case $h$ is SM-like. Note that the alignment limit can be achieved even in a case where $m_H \sim O(v)$.

To make contact with the results of Ref. [14], one can compute $c_{\beta - \alpha} = (c_\beta c_\alpha + s_\beta s_\alpha)$ using Eqs. (14) and (18). Additional simplification can be implemented by noting that $\mathcal{M}^2_{11} + \mathcal{M}^2_{22} = \Delta + 2m_t^2$, which allows us to remove $\Delta$ in favor of $m_h^2$. The end result is

$$c_{\beta - \alpha} = \frac{(\mathcal{M}^2_{11} - m_h^2)c_\beta + \mathcal{M}^2_{12}s_\beta}{\sqrt{(m_H^2 - m_h^2)(\mathcal{M}^2_{11} - m_h^2)}}. \tag{33}$$

The exact alignment condition corresponds to the vanishing of the numerator in Eq. (33), which yields

$$t_{\beta} M_{12} = m_h^2 - M_{11}. \tag{34}$$

Dividing Eq. (34) by $M_{12}$ and using Eq. (14) then gives

$$t_{\beta}^{-1} M_{12} = m_h^2 - M_{22}. \tag{35}$$

Eliminating $m_h^2$ from Eqs. (34) and (35),

$$c_{2\beta} M_{12} = s_\beta c_\beta (M_{11} - M_{22}). \tag{36}$$

Using Eqs. (6)–(10), one can check that Eq. (36) is equivalent to the condition $Z_6 = 0$, where $Z_6$ is given by Eq. (26). In addition, one can use either Eq. (34) or (35) to obtain $m_h^2 = Z_1 v^2$, where $Z_1$ is given by Eq. (24), as expected in light of Eq. (32).

In the 2HDM, the exact alignment limit of $Z_6 = 0$ can be achieved in four possible ways: (i) as a consequence of an exact symmetry of the theory; (ii) as a consequence of an
exact symmetry of the scalar potential, which is broken by the Higgs-Yukawa interactions; (iii) as a consequence of an accidental global symmetry of the scalar potential, which is broken by the gauge interactions and Higgs-fermion Yukawa interactions; or (iv) accidentally due to a choice of scalar potential parameters that is not governed by any symmetry. We exhibit these four possibilities in turn.

An example of case (i) is the inert 2HDM [23]. In this model, the theory possesses an exact $Z_2$ symmetry in the Higgs basis, under which the Higgs basis field $H_2$ is odd and all other fields ($H_1$, fermions and gauge bosons) are even. In this case $Z_6 = 0$ as a consequence of the $Z_2$ symmetry [11], which remains unbroken in the vacuum since $\langle H_2^0 \rangle = 0$.

An example of case (ii) is the 2HDM with the scalar potential parameters of Eq. (1) given by [24,25]

\[
m_{11}^2 = m_{22}^2, \quad \lambda_1 = \lambda_2 = \lambda_3 + \lambda_4 + \lambda_5, \\
m_{12}^2 = \lambda_6 = \lambda_7 = 0. \tag{37}
\]

These conditions on the $\lambda_i$ yield $Z_6 = 0$ [cf. Eq. (26)]. Equation (37) is satisfied by 2HDM scalar potentials with a generalized $CP^3$ symmetry or with an SO(3) Higgs flavor symmetry (the latter if $\lambda_5 = 0$ also holds), as shown in Ref. [24]. In general these two symmetries will not be respected by the Higgs-fermion Yukawa interactions [26].

Custodial symmetric scalar potentials provide examples of case (iii). Indeed, custodial symmetries [27] are broken by the hypercharge gauge interactions as well as by the Higgs-fermion Yukawa interactions. The maximally symmetric 2HDM of Ref. [25] with an SO(5) global symmetry, which yields Eq. (37) with $\lambda_4 = \lambda_5 = 0$, provides an example of this case. In particular, Ref. [25] has stressed the role of the symmetries that lead to Eq. (37), which yields exact alignment at tree level. Deviations from alignment are generated due to loop effects, since these are not exact symmetries of the full theory.

Finally, as we shall see in the next subsection, Eq. (37) does not hold for the MSSM Higgs sector. Thus, alignment can only arise for a special choice of parameters and is not a consequence of any symmetry.

For completeness, we record the Yukawa couplings of the two Higgs doublets to a single generation of up- and down-type quarks. Employing the notation of the third generation,

\[-\mathcal{L}_\text{Yuk} = Y_b^b \tilde{b} R \Phi_1^i Q_L^i + Y_t^t \tilde{t} R \Phi_2^i Q_L^i \\
+ \epsilon_{ij}[Y^j_R t_R \Phi_1^j \Phi_1^i + Y^j_R t_R \Phi_2^j \Phi_2^i] + \text{H.c.}, \tag{38}
\]

where $\epsilon_{12} = -\epsilon_{21} = 1$, $\epsilon_{11} = \epsilon_{22} = 0$, $Q_L = (t_L, b_L)$ are the doublet left-handed quark fields and $t_R, \tilde{b}_R$ are the singlet right-handed quark fields. Inserting $\langle \Phi_1^0 \rangle = v_1/\sqrt{2}$ yields the quark masses

\[m_b = (v_1 Y_b^b + v_2 Y_b^b)/\sqrt{2}, \quad m_t = (v_1 Y_t^t + v_2 Y_t^t)/\sqrt{2}. \tag{39}\]

B. The MSSM Higgs sector

The Higgs sector of the MSSM is a 2HDM whose dimension-four couplings are constrained by supersymmetry. In particular, at tree level,

\[\lambda_1 = \lambda_2 = -(\lambda_3 + \lambda_4) = \frac{1}{4}(g^2 + g'^2) = m_Z^2/v^2, \tag{40}\]

\[\lambda_4 = -\frac{1}{2}g'^2 = -2m_W^2/v^2, \tag{41}\]

\[\lambda_5 = \lambda_6 = \lambda_7 = 0. \tag{42}\]

These results yield the well-known formulas for the tree-level MSSM $CP$-even Higgs masses. At tree level, $\langle m_h^2 \rangle_{\text{max}} = m_Z^2 c_2^2$, which is not consistent with experimental data. However, radiative corrections can have large contributions to the tree-level Higgs mass, and regions of MSSM parameter space can be found where $m_h = 125$ GeV, as required by the data.

The mixing angle, which governs the Higgs couplings, is easily written down using the Higgs basis. Using Eqs. (24) and (26),

\[Z_1 v^2 = m_Z^2 c_2 c_2, \quad Z_6 v^2 = -m_Z^2 s_2 c_2. \tag{43}\]

Inserting the above results into Eq. (30) yields the tree-level result

\[c_{\beta-\alpha} = \frac{m_Z^2 s_2 c_2}{\sqrt{(m_h^2 - m_h^2)(m_h^2 - m_Z^2 c_2^2)}}. \tag{44}\]

In the decoupling limit, one recovers Eq. (31) as expected. In addition, radiative corrections that are required to yield a phenomenologically acceptable value of $m_h$ do not significantly modify the decoupling behavior exhibited above. In contrast, alignment cannot be achieved without decoupling at tree level (except at the end points where either $s_\beta = 0$ or $c_\beta = 0$, for which no tree-level mass is obtained for the up-type and down-type quarks, respectively, and at the midpoint $t_\beta = 1$, which leads to a vanishing lightest $CP$-even Higgs mass at tree level. None of these scenarios are experimentally viable.). We shall see in the next subsection that including radiative corrections, alignment independent of decoupling can be achieved in the MSSM at

---

Note that $\beta$ has been promoted to a physical parameter, since the tree-level coupling relations given in Eqs. (40)–(42) are a consequence of supersymmetry, which establishes a preferred basis choice for the scalar Higgs fields.
values of β away from the end points, resulting in important phenomenological consequences.

Supersymmetry also imposes constraints on the Higgs-fermion interactions. In the supersymmetric literature, it is common to define

\[ H_D^i \equiv e_{ij} \Phi_1^j, \quad H_U^j = \Phi_2^j. \tag{45} \]

In terms of \( H_U \) and \( H_D \), the Yukawa couplings given in Eq. (38) must be holomorphic, which implies that \( \mathcal{Y}_1^l = \mathcal{Y}_2^l = 0 \). This yields the so-called type-II Higgs-quark couplings.\(^5\)

\[-\mathcal{L}_{Yuk} = e_{ij}[h_b \tilde{b}_R H_D^i Q_L^j + h_{tR} \tilde{t}_R H_U^j] + \text{H.c.}, \tag{46} \]

where we have resorted to the more common notation \( h_b = \mathcal{Y}_1^b \) and \( h_t = \mathcal{Y}_2^t \). Equation (39) then yields

\[ m_b = h_b v_c \beta / \sqrt{2}, \quad m_t = h_t v_s \beta / \sqrt{2}. \tag{47} \]

The corresponding tree-level Yukawa couplings of the lightest CP-even Higgs boson to down-type and up-type quark pairs are given by

\[ g_{hhb} = -\frac{m_b s_a}{v} \frac{s_\beta}{c_\beta} = \frac{m_b}{v} (s_\beta - c_\beta t_\beta), \tag{48} \]

\[ g_{hht} = \frac{m_t c_a}{v} s_\beta = \frac{m_t}{v} (c_\beta - s_\beta t_\beta^1). \tag{49} \]

Equations (48) and (49) exhibit the expected behavior in the decoupling and alignment limits. That is, when \( c_\beta - a = 0 \), we recover the SM result \( g_{hhf} = m_f / v \). However, note that in the absence of exact alignment, the deviation from SM couplings of the down-type Yukawa coupling is \( t_\beta \) enhanced. Therefore, it is not enough to demand \( |c_\beta - a| \ll 1 \). Rather, proper SM-like behavior of the coupling of \( h \) to down-type quarks is recovered if \( |c_\beta - a| \ll 1 / t_\beta \). This phenomenon has been called delayed decoupling in Refs. [10,15,28,29].

In the MSSM, the coupling of the Higgs bosons to squarks and sleptons are governed by both supersymmetry-conserving and supersymmetry-breaking parameters. The relevant couplings can be found in Ref. [4]. For later use, we shall focus here on the couplings of \( H_U \) and \( H_D \) to the third-generation squarks that are proportional to the Higgs-top quark Yukawa coupling \( h_t \). The corresponding terms in the interaction Lagrangian are

\[ \mathcal{L}_{int} \supset h_t [\mu^*(\bar{H}_D^i \tilde{Q}^j \bar{U} + A_i e_{ij} H_U^j \tilde{Q}^j \bar{U} + \text{H.c.}]

- h_t^2 [H_D^i H_U^j (\tilde{Q}^j \tilde{Q} \bar{U} + \bar{U}^* \tilde{U}) - |(\tilde{Q}^j H_U^j)|^2], \tag{50} \]

with an implicit sum over the weak \( SU(2) \) indices \( i, j = 1, 2 \), where in the notation of Ref. [4],

\[ \tilde{Q} = \begin{pmatrix} \tilde{t}_L \\ \tilde{b}_L \end{pmatrix}, \quad \bar{U} \equiv \tilde{t}_R, \tag{51} \]

and in general the supersymmetric Higgsino mass parameter \( \mu \) and the supersymmetry-breaking parameter \( A_i \) are complex.

It is convenient to rewrite Eq. (50) in terms of the Higgs basis fields. Using Eqs. (22) and (45), it follows that

\[ \mathcal{L}_{int} \supset h_t e_{ij} [(s_\beta X_i H_D^i + c_\beta Y_i H_D^i \tilde{Q}^j \bar{U} + \text{H.c.}) - h_t^2 [(s_\beta^2 |H_1|^2 + c_\beta^2 |H_2|^2 + s_\beta c_\beta (H_1^* H_2 + \text{H.c.)}) (\tilde{Q}^j \tilde{Q} \bar{U} + \bar{U}^* \tilde{U})

- s_\beta^2 |H_1|^2 - c_\beta^2 |H_2|^2 - s_\beta c_\beta (\tilde{Q}^j H_1^j)(\tilde{Q}^j \tilde{Q} + \text{H.c.})], \tag{52} \]

where

\[ X_i \equiv A_i - \mu^* / t_\beta, \quad Y_i \equiv A_i + \mu^* t_\beta. \tag{53} \]

Note that the terms proportional to \( X_i \) in Eq. (52) are responsible for the mixing of \( \tilde{t}_L \) and \( \tilde{b}_R \) in the top-squark squared-mass matrix; the corresponding off-diagonal element is \( \mathcal{M}_{12}^2 \).\(^6\) After setting \( |H_D^i| = v / \sqrt{2} \) and using Eq. (47). For simplicity, we shall henceforth assume that \( \mu \) and \( A_i \) are real, thereby neglecting possible CP-violating effects that can be introduced into the MSSM Higgs sector via radiative corrections.

\(^6\)As in the previous subsection, we neglect the full generation structure of the Yukawa couplings and focus on the couplings of the Higgs bosons to the third-generation quarks.
limit independent of decoupling is most relevant for \( m_A, m_H < 2m_t \). For heavier values of \( m_A \), the behavior of the Higgs sector approaches that of the decoupling regime.

After integrating out the squarks, the supersymmetric relations that govern the scalar potential parameters [given in Eqs. (40)–(42)] are modified. At one loop, the leading logarithmic corrections, which only appear for \( \lambda_1, \ldots, \lambda_5 \), can be found in Ref. [19]. In addition, threshold corrections proportional to the MSSM parameters, \( A_t, A_b \), and \( \mu \), can also contribute significant corrections to all the scalar potential parameters, \( \lambda_1, \ldots, \lambda_5 \). The relevant expressions are rather lengthy. To get a sense of the corrections, we note that the largest contributions are proportional to the fourth power of the top-quark Yukawa coupling \( h_t \). Using the results given in Ref. [19] (the corresponding leading two-loop corrections to the quartic couplings can be found in Ref. [30]), we obtain the following expressions for \( Z_1, Z_5 \) and \( Z_6 \) [cf. Eqs. (24)–(26)] in the limit of \( m_2, m_A \ll M_S \), which include all one-loop radiative corrections proportional to \( h_t^2 \):

\[
Z_1 v^2 = m_Z^2 c_{2\beta} + \frac{3v^2 s^4 h_t^4}{8\pi^2} \left[ \ln \left( \frac{M_Z^2}{m_t^2} \right) + \frac{X_t^2}{M_S^2} \left( 1 - \frac{X_t^2}{12M_S^2} \right) \right],
\]

(54)

\[
Z_5 v^2 = s_2^2 + \frac{3v^2 h_t^4}{32\pi^2} \left[ \ln \left( \frac{m_Z^2}{m_t^2} \right) + \frac{X_t Y_t}{m_t^2} \left( 1 - \frac{X_t Y_t}{12m_t^2} \right) \right],
\]

(55)

\[
Z_6 v^2 = s_2^2 \left\{ m_Z^2 c_{2\beta} - \frac{3v^2 s^4 h_t^4}{16\pi^2} \left[ \ln \left( \frac{M_Z^2}{m_t^2} \right) \right] \right.

+ \frac{X_t (X_t + Y_t)}{2M_S^2} - \frac{X_t^2 Y_t}{12M_S^2} \right\},
\]

(56)

where \( X_t \) and \( Y_t \) are given by Eq. (53). The upper bound for the squared mass of the lightest \( CP \)-even Higgs boson \( h \) is given by \( (m_h^2)_{\text{max}} = Z_1 v^2 \). Indeed, Eq. (54) exhibits the well-known leading one-loop approximation for the upper bound on \( m_h^2 \) in the MSSM.

The structure of the threshold corrections [proportional to either \( X_t \) or \( Y_t \) in Eqs. (54), (55) and (56)] is easy to understand. For example, in Fig. 1, we exhibit the leading one-loop corrections to \( Z_6 \), which corresponds to the coefficient of the operator \([H_1^+ H_1^+](H_1 H_2) + \text{H.c.} \) [cf. Eq. (23)] in the Higgs basis. Using the interaction Lagrangian given by Eq. (52), one can immediately ascertain the parametric dependence of the diagrams shown in Fig. 1. Each diagram has a \( s^4 c_{2\beta} h_t^4 \) dependence, and there is a factor of \( X_t [Y_t] \) for each \( H_1 Q \bar{U} [H_2 Q \bar{U}] \) vertex, respectively. In this way, we explain the parametric dependence of the threshold corrections to \( Z_6 \) exhibited in Eq. (56). Likewise, by replacing the external \( H_2 [H_1] \) line with an \( H_1 [H_2] \) line in Fig. 1 and deleting graphs (e) and (f), which are now identical to graphs (c) and (d), we can understand the parametric dependence of the threshold corrections to \( Z_1 [Z_5] \).

It is instructive to obtain an approximate one-loop formula for \( c_{\beta\alpha} \), keeping only the leading \( O(h_t^4) \) corrections. We can also simplify the result by considering the large \( t_\beta \) limit. Indeed, the resulting expressions will provide good approximations for \( t_\beta \gtrsim 5 \) (a region of considerable interest in our analysis). In the large \( t_\beta \) limit, we may approximate \( s_\beta = 1 \) and \( c_{\beta\alpha} = -1 \). Moreover, in this approximation the radiatively corrected value of the squared mass of the light \( CP \)-even Higgs boson at one loop is

\[
m_h^2 \approx Z_1 v^2 = m_Z^2 + \frac{3m_t^4}{2\pi^2 v^2} \left[ \ln \left( \frac{M_Z^2}{m_t^2} \right) + \frac{X_t^2}{M_S^2} \left( 1 - \frac{X_t^2}{12M_S^2} \right) \right],
\]

(57)

where we have used Eq. (47) to write \( v^2 s^4 h_t^4 = 4m_t^4 / v^2 \). Using Eqs. (56) and (57) in the evaluation of Eq. (30) yields

\[
t_\beta c_{\beta\alpha} \approx \frac{-1}{m_H^2 - m_h^2} \left[ m_h^2 + m_2^2 \right]

+ \frac{3m_t^4 X_t (Y_t - X_t)}{4\pi^2 v^2 M_S^2} \left( 1 - \frac{X_t^2}{6M_S^2} \right).
\]

(58)

At large \( t_\beta \) we have \( X_t (Y_t - X_t) \approx \mu (A_t t_\beta - \mu) \) and \( X_t^2 (Y_t - X_t) \approx \mu A_t^2 (A_t t_\beta - 3\mu) \), in which case, Eq. (58) can be rewritten in the following approximate form:
The significance of the product $t_\beta c_{\beta-a}$ has already been noted below Eq. (49). Namely, the condition that guarantees that the coupling of $h$ to down-type quarks and leptons is close to its SM value is $|t_\beta|c_{\beta-a} \ll 1$. In contrast, all other couplings approach their SM values for $|c_{\beta-a}| \ll 1$, independently of the value of $t_\beta$.

The Higgs-fermion Yukawa couplings are also modified below the scale $M_S$. Having integrated out the squarks, the low-energy effective Yukawa couplings are no longer of type II (which had been previously enforced by supersymmetry). The Yukawa couplings below the scale $M_S$ have the form given in Eq. (38):

$$ -\mathcal{L}_{Yuk} = e_{ij}[(h_b + \delta h_b)\tilde{b}_R H^*_D Q^L_i + (h_t + \delta h_t)\tilde{t}_R Q^L_i H^*_U] + \Delta h_b \tilde{b}_R Q^L_i H^*_U + \Delta h_t \tilde{t}_R Q^L_i H^*_D + \text{H.c.}, $$

where $\delta h_{t,b}$ and $\Delta h_{t,b}$ represent one-loop contributions from squark or gaugino loops. Equation (60) yields a modification of the tree-level relations between $h_t$, $h_b$, and $m_t$, $m_b$ as follows [31]:

$$ m_b = \frac{h_b v}{\sqrt{2}} c_\beta \left(1 + \frac{\delta h_b}{h_b} + \frac{\Delta h_t t_b}{h_b}\right) = \frac{h_b v}{\sqrt{2}} c_\beta (1 + \Delta_b), $$

$$ m_t = \frac{h_t v}{\sqrt{2}} s_\beta \left(1 + \frac{\delta h_t}{h_t} + \frac{\Delta h_t \cot \beta}{h_t}\right) = \frac{h_t v}{\sqrt{2}} s_\beta (1 + \Delta_t), $$

which define the quantities $\Delta_b$ and $\Delta_t$. Diagonalizing the CP-even Higgs squared-mass matrix, Eqs. (60)–(62) then yield the physical couplings of $h$ to the up-type and down-type quarks. After resummation of the dominant corrections [5,32,33], the resulting expressions can be written in the following forms:

$$ g_{hhb} = \frac{m_b}{v} \left[ s_{\beta-a} - c_{\beta-a} t_\beta \right] - \frac{1}{1 + \Delta_b} \left( \frac{\delta h_b}{h_b} - \Delta_b \right) \left( c_{\beta-a} t_\beta \right), $$

$$ g_{hti} = \frac{m_t}{v} \left[ s_{\beta-a} + c_{\beta-a} t_\beta \right] - \frac{1}{1 + \Delta_t} \frac{\Delta h_t h_t}{h_t} \left( s_{\beta-a} \right). $$

The dominant contributions to $\Delta_b$ are $t_\beta$ enhanced, with $\Delta_b = (\Delta h_b / h_b) t_\beta$; for $t_\beta \gg 1$, $\delta h_b / h_b$ provides a small correction to $\Delta_b$. In the same limit, $\Delta_t = \delta h_t / h_t$, with the additional contribution of $(\Delta h_t / h_t) \cot \beta$ providing a small correction. In practical applications, it is often sufficient to keep only $\Delta_b$, which provides the dominant contributions to the radiatively corrected Yukawa couplings.

Note that the radiative corrections to the couplings of $h$ to the up-type and down-type quarks vanish in the limit of exact alignment where $c_{\beta-a} = 0$. However, the phenomenon of delayed decoupling at large $t_\beta$, discussed below Eq. (49), persists. That is, at large values of $t_\beta$, the $hbb$ coupling approaches the corresponding SM value in the limit of $t_\beta|c_{\beta-a}| \ll 1$.

C. Alignment independent of decoupling in the MSSM Higgs sector

In the previous section, we noted that alignment independent of decoupling is not possible for the tree-level MSSM Higgs sector, since $Z_b v^2 = -m_Z^2 s_{2\beta} c_{2\beta} \neq 0$, except at phenomenologically unacceptable values of $\beta$. Once radiative corrections are included, alignment independent of decoupling can occur quite generically, due to the appearance of a branch of solutions that are absent at tree level [14].

To explicitly check the cancellation that yields alignment, we make use of the fact that exact alignment is attained when $Z_b = 0$. Assuming that $s_{2\beta} \neq 0$, it then follows from Eq. (56) that exact alignment at one-loop order is achieved when

$$ m_Z^2 c_{2\beta} = \frac{3 v^2 s_{2\beta} h_t^4}{16 \pi^2} \left[ \ln \left( \frac{M^2}{m^2} \right) + \frac{X_t (X_t + Y_t)}{2 M^2} - \frac{X_t^2 Y_t}{12 M_f^2} \right], $$

where $X_t$ and $Y_t$ are defined in Eq. (53). Equation (65) yields a nonlinear polynomial equation for $t_\beta$. If a solution exists for positive $t_\beta$ (recall that $0 \leq \beta \leq \frac{\pi}{2}$ by convention) for fixed values of the other MSSM parameters, then the alignment limit can be realized. To exhibit that a solution is possible, we shall assume that $t_\beta \gg 1$ (in practice, moderate to large values of $t_\beta \gtrsim 5$ are sufficient). We then perform a Taylor expansion of Eq. (65) keeping only constant terms and terms linear in $t_\beta^{-1}$. We can then easily solve for $t_\beta$:

$$ t_\beta = \frac{m_Z^2 + \frac{3 v^2 h_t^4}{16 \pi^2} \left[ \ln \left( \frac{M^2}{m^2} \right) + \frac{24 A^2 - m^2}{2 M^2} - \frac{24 (A - 2 m^2)}{12 M^2} \right]}{3 v^2 h_t^4 A_t^2 (6 M_f^2 - 1)}. $$

Since we have assumed that $t_\beta \gg 1$ in deriving Eq. (66), we can rewrite this result in terms of $m_Z^2$ [cf. Eq. (57)] and $m_t^2$ (after taking $s_\beta = 1$):

$$ t_\beta = \frac{m_Z^2 + \frac{3 m_t^2}{4 \pi^2 v^2 M^2} (A_t^2 - 1)}{3 m_t^2 v A_t (6 M_f^2 - 1)}. $$

As a check of Eq. (67), one can verify that the same result is obtained by setting the approximate expression of $c_{\beta-a}$ obtained in Eq. (59) to zero.
For values of $\mu$, $A_t \sim O(M_S)$, the term of $O(m^4)$ in the numerator of Eq. (67) is subdominant. Since $t_\beta$ is positive, it follows that a viable solution exists if $\mu A_t (A_t - \sqrt{6}M_S) > 0$. In the approximations employed in obtaining Eq. (57), the so-called maximal mixing condition, that yields the largest radiatively corrected Higgs mass, corresponds to $A_t = \sqrt{6}M_S$. Moreover, one obtains $t_\beta \gg 1$ if $\mu A_t > 0$ ($\mu A_t < 0$) with values of $A_t$ not too far above (below) the maximal mixing condition, which is consistent with the assumption used in the derivation of Eq. (67).

To make contact again with the results of Ref. 14, we observe that the exact alignment condition, $Z_6 = 0$, is achieved when [cf. Eq. (26)]

$$
(\lambda_1 - \lambda_{345})c_\beta^2 - (\lambda_2 - \lambda_{345})s_\beta^2 = (c_\beta^2 - 3s_\beta^2) t_\beta^{-1} \lambda_6 + (3c_\beta^2 - s_\beta^2) t_\beta \lambda_7,
$$

(68)

where $\lambda_{345} \equiv (\lambda_3 + \lambda_4 + \lambda_5)$. For $t_\beta \gg 1$, we can approximate $c_\beta \sim t_\beta^{-1} = 0$ and $s_\beta = 1$. We then obtain Eq. (103) of Ref. 14:

$$
t_\beta = \frac{\lambda_2 - \lambda_{345}}{\lambda_7}.
$$

(69)

The value of $t_\beta$ at which alignment takes place is inversely proportional to $\lambda_7$, which vanishes in the MSSM at tree level and arises only radiatively. As can be seen from Eq. (69), alignment at smaller $t_\beta$ requires a larger $\lambda_7$, unless there is a tuning between $\lambda_2$ and $\lambda_{345}$ in the numerator. In the end, it was found in Ref. [14] that for generic choices of parameters in the MSSM, alignment independent of decoupling typically occurs at some value of $t_\beta \gtrsim 10$, with smaller $t_\beta$ requiring larger values of $A_t/M_S$ and $\mu/M_S$ [cf. Eq. (66)].

For top squark masses of the order of a few TeV, the requirement of obtaining the proper value of $m_t$ constrains the values of $A_t \lesssim 3M_S$. In Ref. [14] it was demonstrated that alignment independent of decoupling may be obtained for $t_\beta$ of order 10 for large values of $\mu \gtrsim 2M_S$ and for either positive values of $A_t$ of about $3M_S$ or negative values of $A_t \approx -1.5M_S$. Alignment values of $t_\beta < 10$ are not easily realized in the MSSM. 9

### III. SEARCHES FOR HEAVY HIGGS BOSONS

Our purpose is to study the interplay of direct searches and precision Higgs measurements in scenarios where alignment occurs at very large versus moderate $t_\beta$. In order
to analyze the bounds on the nonstandard Higgs masses, we choose benchmark scenarios close to the ones proposed in Ref. [35], which are used by the LHC experimental collaborations in their analyses of searches for nonstandard Higgs bosons (see, for example, Refs. [36,37]). Specifically, in Table I we define two classes of benchmarks, $m^\text{mod+}$ and $m^\text{alt}$, where the main difference with the $m^\text{mod+}$ and the tau-phobic scenarios defined in Ref. [35] is that we take $\mu$ and $m_Q$ as floating parameters.

These two classes of scenarios differ in the choice of the ratio $A_t/m_Q$, which results in no alignment or alignment at very large values of $t_\beta$ for $m^\text{mod+}$ and alignment at $t_\beta \lesssim 50$ for $m^\text{alt}$ [14]. Although these benchmarks are inspired by those proposed in Ref. [35], the fact that we allow the $\mu$ parameter and the overall soft scale $m_Q$ to vary allows us to obtain the correct mass for the lightest CP-even Higgs boson at small $t_\beta \lesssim 6$ and to study the impact of alignment at different values of $t_\beta$. Both have a crucial impact on the properties of the lightest CP-even Higgs boson and on the decays of the heavy CP-even and CP-odd Higgs bosons.

Observe also that we fix the value of $A_t$ instead of $X_t$, as was done in Ref. [35], which makes a difference only at large values of $\mu$ and small values of $t_\beta \lesssim 10$. In particular our $m^\text{mod+}$ scenario with $\mu = 200$ GeV has the same properties as the $m^\text{mod+}$ scenario in Ref. [35] and we have therefore adapted the notation from that reference. All of our numerical results are obtained from FENNYHIGGS [38], which allows for a computation of all the relevant production cross sections and branching ratios.

Before discussing the details of the Higgs phenomenology, recall the approximate analytical expressions given in the previous section governing the behavior of the various couplings, for example, $c_{\beta-\alpha}$ obtained in Eq. (59). In our benchmark scenarios, $m_Q$ denotes the common squark or slepton mass, and hence one can identify $M_S = m_Q$. It should be noted that Eq. (59) does not include two-loop corrections, which can be significant. These two-loop corrections approximately preserve the parametric dependence of our analytic expressions on $A_t/m_Q$ in the $\overline{\text{MS}}$ and

TABLE I. Parameters in the on-shell scheme defining the $m^\text{mod+}$ and $m^\text{alt}$ scenarios. We leave $m_Q$ and $\mu$ as floating parameters.

<ref>PHYSICAL REVIEW D 91, 035003 (2015)</ref>

<ref>CAREN A et al.</ref>

9Using the radiatively corrected expressions for the couplings in Eq. (69) given in Ref. [19], keeping only terms proportional to $h^4_{\text{UV}}$ we recover the expression given in Eq. (66).

Alignment independent of decoupling for smaller values of $t_\beta$ may be obtained in the NMSSM [14] or in triplet extensions of the MSSM [34].

10It should be noted that there are relevant difference between the results obtained by FENNYHIGGS and other higher order computations [39-41], but the analysis of the origin of these differences is beyond the scope of this article.
schemes. This is not true in the on-shell scheme, which is employed in FEYNHIGGS. Therefore, in comparing our analytic expressions with our numerical results, one should use the values of \( \Lambda_t = m_Q \) in the \( \overline{\text{MS}} \) or \( \text{DR} \) schemes, that are approximately 20% larger than the ones in the on-shell scheme [8].

A. Getting the correct \( m_h \) everywhere

In scenarios defined previously in Ref. [35], top squark masses are fixed at the order of 1 TeV, which fails to reproduce the proper lightest \( CP \)-even Higgs mass, \( m_h \approx 125 \) GeV, at values of \( t_\beta \leq 6 \) (the precise value of \( t_\beta \) at which this occurs depends on the specific scenario). In our benchmarks we vary the overall top squark mass scale \( m_Q \) so that the lightest \( CP \)-even Higgs mass is in the experimentally observed range within theoretical uncertainties, which we take to be of the order of 3 GeV, \( m_h = 125 \pm 3 \) GeV. More specifically, for a given value of \( t_\beta, \mu/m_Q \) and \( A_t/m_Q \), we fix the value of \( m_Q \) for small values of \( m_A \approx 200 \) GeV in such a way that the lightest \( CP \)-even Higgs mass is about 123 GeV. This is enough to keep the value of \( m_h \) in the acceptable range for all values of \( m_A \). The small variation of the lightest \( CP \)-even Higgs mass for larger values of \( m_A \) has only a minor impact on the heavy Higgs phenomenology and does not affect the signal strength of the lightest \( CP \)-even Higgs in any significant way. In contrast, fixing the value of \( m_Q \) at around 1 TeV, as currently done by the experimental collaborations, leads to artificially low values of \( m_h \) at low values of \( t_\beta \) that can have a large impact on the Higgs boson phenomenology.

The corresponding values of the top squark soft breaking mass parameters, \( m_Q \), are displayed in Fig. 2. Observe that for the \( m_{h}^{\text{alt}} \) scenario (apart for the case of \( \mu = 3m_Q \)), larger values of \( m_Q \) are necessary for smaller values of \( \mu \), while in the \( m_{h}^{\text{mod+}} \) scenario, larger values of \( m_Q \) are obtained for larger values of \( \mu \). The reason for this behavior is that generally in the \( m_{h}^{\text{alt}} \) scenario, larger values of \( \mu \) approach the top squark mixing for which the lightest \( CP \)-even Higgs mass is maximized, \( X_t = A_t - \mu/t_\beta = 2m_Q \), in the on-shell scheme. This implies the need for smaller logarithmic corrections and therefore smaller values of \( m_Q \). The exception is the case of \( \mu = 3m_Q \), where \( \mu \) is so large that at small values of \( t_\beta \), \( X_t \) is already smaller than the maximal value for the Higgs mass. As \( t_\beta \) increases, \( X_t \) increases, approaching the maximal value from the other side. This explains the different dependence on \( m_Q \) for this case. In the \( m_{h}^{\text{mod+}} \) scenario, larger values of \( \mu \) imply values of \( X_t \) further away from maximal mixing, which in turn require larger values of \( m_Q \) to obtain the correct \( m_h \).

B. Decay branching ratios of heavy Higgs bosons

In Fig. 3 we show the variation in the decay branching ratios of the heavy neutral Higgs bosons, \( H \) and \( A \), in the \( m_{h}^{\text{alt}} \) scenario for small values of \( \mu \), and for moderate values of \( t_\beta = 10 \) and small values of \( t_\beta = 4 \); the results in the \( m_{h}^{\text{mod+}} \) scenario for the same values of \( \mu \) are very similar.
and will not be shown here. At larger values of $\mu$, the distinction between the two scenarios becomes more prominent as shown in Figs. 4 and 5.

We first examine the case of small $\mu$. For $\tan \beta = 10$, the decays into bottom quarks represent the dominant decay mode of the heavy Higgs bosons at small values of $m_{A,H}$. At the largest values of the nonstandard Higgs boson masses shown in Fig. 3, the decays of the heavy Higgs bosons into charginos and neutralinos become prominent, suppressing the branching ratio of the decays of the nonstandard Higgs bosons into $b\bar{b}$ and $\tau^+\tau^-$. For $\tan \beta = 4$, one interesting feature is that the decay of $H$ into pairs of lightest $CP$-even $H$ becomes significant at masses above the corresponding kinematic threshold, a property that persists even when the value of $\mu$ is changed, as shown in Fig. 5. Another important feature is that the
$H/A$ decay into pairs of neutralinos and charginos becomes prominent throughout the mass range we consider, thereby suppressing the decay branching ratios into the canonical search channels $b\bar{b}$ and $\tau^+\tau^-$. In particular, the branching ratio of the heavy Higgs bosons into tau-lepton pairs, which is the main focus of present searches, never exceeds 5% and is quite suppressed for $m_{A,H} \gtrsim 300$ GeV.

Next we compare the decay branching ratios in the $m_h^{\text{mod}+}$ and $m_h^{\text{alt}}$ scenarios for large values of $\mu$. Figure 4 shows the comparison at $\tan\beta = 10$ while Fig. 5 is for $\tan\beta = 4$. One important consequence of raising $\mu$ is that the Higgsinos become heavy, resulting in small couplings of the light gauginolike charginos and neutralinos to the neutral Higgs bosons. Therefore, the decays into

---

**FIG. 4 (color online).** Branching ratios of the heavy $CP$-even (left panels) and $CP$-odd (right panels) Higgs bosons as a function of their respective masses for $\tan\beta = 10$ in the $m_h^{\text{alt}}$ scenario (top panels) and $m_h^{\text{mod}+}$ scenario (bottom panels), for large values of the Higgsino mass parameter, $\mu = m_Q$. 
electroweakinos are always suppressed, never exceeding a few percent. At $t_\beta = 10$ the decays into bottom-quark and tau-lepton pairs become prominent for all values of the heavy Higgs boson masses.

For $t_\beta = 4$, the branching ratio of the decay of the heavy neutral Higgs bosons into bottom quarks and tau leptons is suppressed due to the decrease of the couplings of down-type fermions to these Higgs bosons. Hence, for $t_\beta = 4$, the $H \to hh$ decay becomes the dominant mode for $m_H$ larger than the kinematic threshold of $2m_h$, until the top channel opens up and becomes the main decay mode. Even below the $2m_h$ threshold, the decay width of the heavy $CP$-even Higgs boson into weak gauge bosons is large enough to suppress the $BR(H \to \tau^+\tau^-)$ to values of order of 5% in

---

FIG. 5 (color online). Branching ratios of the heavy $CP$-even (left panels) and $CP$-odd (right panels) Higgs bosons as a function of their respective masses for $t_\beta = 4$ in the $m_h^{alt}$ scenario (top panels) and $m_h^{mod+}$ scenario (bottom panels), for large values of the Higgsino mass parameter, $\mu = m_Q$. 
both scenarios. As for the CP-odd Higgs boson, as can be seen in the right panels of Fig. 5, due to the absence of any relevant contribution to the total decay width beyond the bottom-quark and tau-lepton final states, the $\text{BR}(A \rightarrow \tau^+\tau^-)$ remains of the order of 10% up to the top quark pair decay threshold. It is worth noting that although the $hZ$ channel becomes significant when the kinematics allow, for the same masses of the heavy Higgs bosons, $\text{BR}(A \rightarrow hZ)$ is always significantly lower than $\text{BR}(H \rightarrow hh)$. These differences between the CP-even and CP-odd Higgs bosons have important phenomenological consequences that will be discussed below.

C. Inclusive production rates of heavy Higgs bosons in the $\tau^+\tau^-$ channel

At the LHC we only measure the total rate, i.e. the production cross section times the branching fraction into some specific final state. In particular, the strongest constraints in the MSSM on the $m_A-t_\beta$ plane are derived using searches in the $\tau^+\tau^-$ final states, which we focus on in this subsection. The main production modes for the heavy neutral Higgs bosons, $A$ and $H$, are the gluon fusion channel and, at moderate or large values of $t_\beta$, associated production with bottom quarks. At large $t_\beta$, the main contribution to the gluon fusion cross section comes from bottom quark loops, since the heavy Higgs couplings to $b$ quarks are enhanced by $t_\beta$. Then the total production cross section is proportional to the square of the bottom Yukawa coupling. However, as $t_\beta$ decreases, the bottom coupling decreases while the top coupling to the nonstandard Higgs bosons increases with $1/t_\beta$. Therefore, at values of $t_\beta \lesssim 6$, the dominant contribution to the gluon fusion production cross section is proportional to the square of the top coupling to the heavy neutral Higgs bosons and becomes significant.

The left panel of Fig. 6 shows the dependence of the inclusive production cross section times the branching ratio of the decay of each neutral heavy Higgs boson into $\tau^+\tau^-$, for $m_A = 300$ GeV, in the $m_A^{\text{alt}}$ and the $m_A^{\text{mod+}}$ scenarios for different values of $\mu$. The solid lines display the behavior of the heavy CP-even Higgs boson and the dashed lines exhibit the corresponding CP-odd Higgs boson cross sections. The behavior of the Higgs-induced $\tau^+\tau^-$ production may be described using the properties of the production cross section and branching ratios discussed above. At large values of $\mu$, the CP-odd Higgs boson decay branching ratio into $\tau^+\tau^-$ remains large and approximately constant for all values of $t_\beta$, and hence the total production rate into $\tau^+\tau^-$ closely follows the CP-odd Higgs production cross section. The increase of the production rate for the CP-odd Higgs boson into $\tau^+\tau^-$ at low values of $t_\beta$ and large $\mu$ is clearly seen in Fig. 6. Also visible is the fact that as $t_\beta$ decreases, the CP-even Higgs contribution to the $\tau^+\tau^-$ production rate is suppressed. This happens due to a decrease of the corresponding branching ratio, compensating for the increase in the gluon fusion production cross section. The same happens for the CP-odd Higgs boson at low values of $\mu$.

The reach of the LHC in this channel at low values of $t_\beta$ and $m_A = 300$ GeV becomes very different as one varies the $\mu$ parameter. For high values of $\mu$, the total production rate into $\tau^+\tau^-$ reaches a minimum at $t_\beta \approx 6$ and then increases for lower values of $t_\beta$, as shown in the right panel.

![FIG. 6 (color online). Inclusive production cross section times branching ratio in the $\tau^+\tau^-$ mode for $m_A = 300$ GeV. The black dashed line in the right panel denotes the extracted upper limit from CMS bounds presented in Ref. [36].](image-url)
of Fig. 6. This is due to the CP-odd Higgs contribution as discussed above and shown in the left panel of Fig. 6. However, at low values of $\mu$, the inclusive production rate into $\tau^+\tau^-$ keeps decreasing for decreasing values of $t_\beta$, as also shown in the right panel of Fig. 6. The horizontal dashed line in the right panel of Fig. 6 denotes an upper $\tau_{\mathrm{.ncbi}}$ into $\tau_{\mathrm{.ncbi}}$ also shown in the right panel of Fig. 6. The horizontal dashed line will be pushed towards smaller values if no scalar resonances are seen. If for a particular value of the mass of the heavy CP-even and CP-odd Higgs bosons the limit were pushed below the minimum of the inclusive $\tau^+\tau^-$ production rate in the large $\mu$ case, that particular value of the Higgs boson mass would be excluded by the data for all values $t_\beta$. This is not possible for the low $\mu$ scenarios, for which no minimum of the production cross section is present.

At lower values of $m_A \approx 200$ GeV the difference between low and high values of $\mu$ becomes less dramatic. Still, as can be seen from Figs. 4 and 5, at $t_\beta = 4$, $\mathrm{BR}(A \to \tau^+\tau^-)$ remains of order 10% for large values of $\mu$ and becomes about half of that value for low values of $\mu$. In contrast, $\mathrm{BR}(H \to \tau^+\tau^-)$ is always somewhat suppressed due to the presence of the decay of the heavy CP-even Higgs into $VV$, suffering an additional suppression at low values of $\mu$. In this particular example at $t_\beta = 4$, $\mathrm{BR}(H \to \tau^+\tau^-)$ is of order 6% for high values of $\mu$ and is reduced to about 3% for low values of $\mu$. Hence, in this case the largest $\tau^+\tau^-$ production contribution comes from the CP-odd Higgs boson.

**D. Rescaling current LHC limits**

We use the procedure discussed in Appendix A to convert the $m_A-t_\beta$ limits presented by the experimental collaborations for a specific scenario, into limits on the inclusive production rate into $\tau^+\tau^-$ for a given value of $m_A$. We then demand that any other scenario we are considering leads to an inclusive production rate which is smaller than this extracted limit. In this way, we are able to obtain a simple rescaling algorithm for the values of $t_\beta$ excluded in any given scenario. The outcome of such a procedure is presented in Fig. 7, which shows the exclusion limits on the $m_A-t_\beta$ plane in our $m_h^{\text{alt}}$ scenario for two different choices of the $\mu$ parameter. As stressed in the last section, an important distinction in going from small to large values of $\mu$ is that the Higgsinos become heavy and therefore the decays of the heavy Higgs bosons into neutralino and/or chargino pairs are suppressed, resulting in a larger branching fraction into $\tau^+\tau^-$ channels. It is clear that, due to the increase in the $\tau^+\tau^-$ production rate for larger values of $\mu$ (see Fig. 6), the exclusion limit may be extended to smaller values of $t_\beta$.

As previously noted, the existence of a minimum in the inclusive production rate for the $\tau^+\tau^-$ channel as a function of $t_\beta$ for large values of $\mu$ (cf. Fig. 6) means that if this minimum falls below the experimental upper bound in the future, one would exclude all $t_\beta$ for a particular value of $m_A$ in the scenario under consideration. Indeed, in Ref. [42] it was shown that for heavy supersymmetric particles, the LHC has the capability of probing the wedge region by means of the $H, A \to \tau^+\tau^-$ channel in the 14 TeV run. However, since this minimum does not exist for the low $\mu$ scenarios, even at 14 TeV, it is unlikely that the LHC would be able to completely probe the low $m_A-t_\beta$ region for these cases.

In Fig. 8 we show the projected limits in the $m_h^{\text{mod+}}$ scenario, with $\mu = 200$ GeV, that are required to exclude all values of $t_\beta$ in scenarios with large $\mu$ for $m_A < 350$ GeV. More explicitly, if in the future the exclusion limit in the $m_h^{\text{mod+}}$ scenario, with $\mu = 200$ GeV, reaches the dashed (dotted) lines, the $m_h^{\text{alt}}$ benchmark, with $\mu = m_Q(m_Q/2)$, would be completely ruled out, respectively. The situation for all our benchmarks with other choices of $\mu$ is similar, as long as $\mu \sim \mathcal{O}(m_Q)$ or larger. For comparison, the solid line in Fig. 8 represents the current bound from the LHC8 in Ref. [36].
and (depending on the mass difference) an enhancement of the decay of the second neutralino into the next-to-lightest neutralinos and the lightest charginos. This will lead to final states associated with the low \( \mu \) scenario. Note that in this paper we have assumed that all squark masses are of the order of the top squark masses, and hence the next-to-lightest neutralinos and the lightest charginos would mostly decay into the lightest neutralino and \( \mu \) parameter, we now focus on its couplings to massive gauge bosons \( h \rightarrow V V \), which are measured quite well experimentally. Another possibility is to use loop-induced couplings such as the diphoton coupling. Indeed, the different values of \( A_t \) and \( \mu \) chosen in the \( m_{h}^{mod+} \) and \( m_{h}^{mod-} \) scenarios lead to deviations in the loop-induced couplings. However, as is demonstrated in Appendix B, the constraining power between these two couplings does not differ significantly.

It is worth emphasizing again that in order to study the complementarity between precision measurements and direct searches, it is important to obtain the correct mass for the lightest \( CP \)-even Higgs boson, which has a major impact on the properties of the 125 GeV Higgs boson and on the decays of the heavy Higgs bosons. As we showed in Sec. III A, in the region of interests where both \( t_\beta \) and \( m_A \) are small, the value of \( m_{h} \) should be raised to values larger than 1 TeV in order to obtain the proper lightest \( CP \)-even Higgs mass values.

Under the assumption of \( |c_{\beta-\alpha}| \ll 1 \), it follows from the results of Sec. II that

\[
g_{hVV} \approx g_{hVV}^{SM}, \quad g_{htt} \approx g_{htt}^{SM},
\]

whereas

\[
g_{hbb} \approx g_{hbb}^{SM}(1 - c_{\beta-\alpha}t_\beta),
\]

where for simplicity we have neglected the \( \Delta_\beta \) and \( \delta h_\beta \) effects in Eq. (63). This implies that, apart from small corrections coming from the squark loops contributing to the gluon-gluon fusion production, the lightest \( CP \)-even Higgs production cross section is SM-like. Moreover, the decay branching ratios of the lightest \( CP \)-even Higgs boson are mostly affected by the modification of the bottom and \( \tau \) couplings. Inspection of Eq. (59) reveals that the down-type quark (and lepton) Yukawa couplings can significantly deviate from their corresponding SM values at low \( m_A \) and moderate values of \( t_\beta \). Moreover, for small values of \( \mu \) these modifications are only weakly dependent on \( t_\beta \), while for large values of \( \mu \), a dependence on \( t_\beta \) appears that may lead to alignment for the specific value of \( t_\beta \) at which \( c_{\beta-\alpha} = 0 \).

In Fig. 9, we summarize our results on the comparison of direct searches for nonstandard Higgs bosons and the precision studies of the lightest \( CP \)-even Higgs boson at the 8 TeV LHC. The dashed contours correspond to various

125 GeV. The value of \( \mu/m_Q \) plays an important role in determining the value of \( t_\beta \) at which alignment occurs, as can be seen in Eq. (66). We shall show that the low \( t_\beta \) and low \( m_A \) region, which is difficult to probe in direct searches at low values of \( \mu \), results in deviations in the properties of the 125 GeV Higgs boson that are quite significant. Therefore, direct searches and precision Higgs measurements are complementary to each other.

In studying properties of the lightest \( CP \)-even Higgs boson, we will focus on its couplings to massive gauge bosons \( h \rightarrow V V \), which are measured quite well experimentally. Another possibility is to use loop-induced couplings such as the diphoton coupling. Indeed, the different values of \( A_t \) and \( \mu \) chosen in the \( m_{h}^{mod+} \) and \( m_{h}^{mod-} \) scenarios lead to deviations in the loop-induced couplings. However, as is demonstrated in Appendix B, the constraining power between these two couplings does not differ significantly.

IV. PRECISION \( h \) MEASUREMENTS VERSUS \( H \) AND \( A \) DIRECT SEARCHES

After analyzing the direct search constraints in the two classes of benchmarks with a varying \( \mu \) parameter, we now study the interplay between direct searches and measurements of properties of the lightest \( CP \)-even Higgs boson at
assumptions on the precision of the signal strength $\sigma(gg \to h) \times \text{BR}(h \to VV)$. For example, the 0.8 contour corresponds to a signal strength that is 80\% of the predicted SM value, etc. The four panels represent four different values for the $\mu$ parameter, and in each panel we depict both the $m_{h}^{\text{mod+}}$ and the $m_{h}^{\text{alt}}$ scenarios. At low values of $\mu$, in light of the weak dependence of the light CP-even Higgs decay branching ratios on $t_{\beta}$, precision studies of the decay branching ratios of the lightest CP-even Higgs lead to a lower bound on the value of $m_{A}$, which is roughly independent of $t_{\beta}$. Indeed, the dashed contours in Fig. 9(a) are nearly vertical, ruling out the parameter space to the left of the corresponding contours. The ATLAS experiment has performed such an analysis and found a bound on $m_{A}$ of order 400 GeV. Let us remark in passing that the signal strength of the $h \to VV$ modes observed at ATLAS is $1.3 \pm 0.2$ and hence according to the results of Fig. 9(a) the bound on $m_{A}$ would be larger than the corresponding one using CMS data, for which the signal strength is $1.0 \pm 0.2$. 

FIG. 9 (color online). Dashed contours show deviations of the signal strength into massive gauge bosons for the lightest CP-even Higgs boson with respect to the SM values in the $m_{h}^{\text{mod+}}$ (blue line) and $m_{h}^{\text{alt}}$ (red line) scenarios in the $m_{A}$-$t_{\beta}$ plane for different values of $\mu$. Shaded regions denote parameters excluded by direct searches for heavy CP-even and CP-odd Higgs bosons decaying into pairs of $\tau$ leptons.
As the value of \( \mu \) is increased we see two effects. On one hand, the contours of constant \( h \)-induced \( VV \) production cross section are drastically modified in the \( m_h^{\text{alt}} \) scenario, due to a relevant dependence on \( t_\beta \) of the bottom quark and tau lepton Yukawa couplings [cf. Eqs. (59) and (71)]. These contours bend to the left in relation with the ones in the \( m_h^{\text{mod}+} \) scenario, becoming almost independent of \( m_A \) at values of \( t_\beta \) close to the alignment limit. Therefore, for \( t_\beta \) close to the value where the alignment condition is satisfied, precision measurements alone are not able to place any bound on \( m_A \). The smallest value of \( t_\beta \) where the alignment condition is satisfied takes place for the largest value of \( \mu = 3m_Q \) considered, shown in Fig. 9(d). Indeed it is difficult to obtain smaller values of \( t_\beta \) at alignment in the MSSM without taking extreme values of the MSSM parameters. Large values of \( A_t/m_Q \) and \( \mu/m_Q \) can lead to charge and color breaking vacua which would bring the stability of the electroweak vacuum into question [47].

The complementarity of the precision \( h(125) \) data with direct searches for nonstandard Higgs bosons is now clear. At the large values of \( t_\beta \) where the alignment condition is satisfied, searches for nonstandard Higgs bosons become effective and, as discussed in the previous section, they become more effective for larger values of \( \mu \). This is shown by the shaded regions of Fig. 9, which denote the CMS limits in the \( m_h^{\text{mod}+} \) and \( m_h^{\text{alt}} \) scenarios. The combination of direct and indirect searches allow us to constrain values of \( m_A \) lower than 250 GeV in the \( m_h^{\text{alt}} \) scenario with \( \mu \lesssim 3m_Q \), independently of \( t_\beta \). Moreover, due to the increase in sensitivity of the search for nonstandard Higgs bosons at large values of \( \mu \), the whole region of parameters for \( m_A \) < 350 GeV is expected to be probed by the LHC in the near future, showing again the strong complementarity between precision studies of the lightest \( CP \)-even Higgs boson, which become a weaker probe in this scenario, and direct searches for nonstandard Higgs bosons.

In summary, at low values of \( \mu \), precision measurements of the lightest \( CP \)-even Higgs bosons are able to probe low values of \( m_A \), independently of \( t_\beta \). In contrast, in the presence of alignment which occurs for large values of \( \mu \), precision measurement studies alone will not be able to put a model-independent bound on \( m_A \). However, in this case direct searches for nonstandard Higgs bosons will be able to probe all values of \( t_\beta \) for values of \( m_A \) below the top-quark decay threshold in the near future.

In Fig. 9(d), we have suppressed additional dashed red contour lines that reappear in the \( m_h^{\text{alt}} \) scenario with \( \mu = 3m_Q \) in the large \( t_\beta \), low \( m_A \) parameter regime. In this regime, the magnitude of the \( hbb \) coupling is once again SM-like, but its sign is flipped relative to that of the \( hvV \) coupling. This wrong-sign \( hbb \) coupling regime, discussed in detail in Ref. [29], cannot be ruled out by the present \( h(125) \) data alone but is completely incompatible with the limits on the \( H \) and \( A \) direct searches via the \( \tau^+\tau^- \) channel.

V. CONCLUSIONS

In this paper, we have analyzed the complementarity between precision measurements of the lightest \( CP \)-even Higgs boson and direct searches for nonstandard Higgs bosons in the MSSM. We have stressed that in the alignment limit, one can significantly relax the bounds on the heavy Higgs bosons that arise from the measurements of the \( VV \) decays of the lightest \( CP \)-even Higgs boson. Such alignment conditions, however, are associated with large values of the \( \mu \) parameter and the top squark mixing parameter, \( A_t \), and tend to be restricted to values of \( t_\beta \) of order 10 or larger within the MSSM.

Direct searches for nonstandard neutral Higgs bosons provide strong constraints on the Higgs spectrum. Currently, the most sensitive search channel is associated with the \( \tau^+\tau^- \) final state, with the main production mode being either through the gluon fusion process or in association with bottom quarks. The ATLAS and CMS experiments have placed lower bounds on \( m_A \) that range from values of order 200 GeV for \( t_\beta \approx 10 \) up to values of order of a TeV for \( t_\beta \approx 50 \). The lower values of \( m_A \) and \( t_\beta \) may be consistent with the observed lightest \( CP \)-even Higgs properties, provided one is not far from the alignment condition. The values of \( \mu \) associated with the alignment limit reduce the decay rate into charginos and neutralinos and therefore increase the BR\((H,A \to \tau^+\tau^-)\), making direct searches more efficient. This property provides an interesting complementarity between direct searches and precision measurements which will allow one to probe the region of \( m_A < 350 \) GeV for all values of \( t_\beta \) in future running of the LHC.

APPENDIX A: INTERPRETING CURRENT BOUNDS FROM LHC8

In Ref. [36] where CMS presented bounds on the heavy Higgs bosons in the MSSM, the limits were derived in particular benchmarks that differ from the two classes of scenarios we are considering in this work. As such, these limits cannot be applied in a straightforward manner. However, Ref. [36] also provided model-independent limits that could be translated into limits in benchmarks considered in this study. The model-independent limits are provided as two-dimensional contours in the plane of the production cross sections via gluon fusion and associated production with bottom quarks. These limits are derived from searching for a heavy scalar resonance in the $\tau^+\tau^-$ final state, independently of any specific model, and show very little contamination from a 125 GeV Higgs boson once the postulated heavy resonance is heavier than 200 GeV.

Unlike the model-independent bounds, the limits in the MSSM benchmarks in Ref. [36] are given in terms of $m_A$ and $t_\beta$, instead of direct upper bounds on the $\tau^+\tau^-$ production rates. We will specifically use the exclusions presented for the $m_h^{mod_-+}$ scenario, with $\mu = 200$ GeV, as a function of $t_\beta$. The production rates in the $m_h^{alt}$ scenario, for $\mu = m_Q$, are displayed as a solid red curve, while the corresponding values in the $m_h^{mod_-+}$ scenario, for $\mu = 200$ GeV, are displayed as a solid blue curve. We show results for $m_A = 200$ GeV and $m_A = 300$ GeV in the left and right panels of Fig. 10, respectively. The corresponding values of $t_\beta$ are displayed as solid dots on these curves. These show that, while in the $m_h^{mod_-+}$ scenario, with $\mu = 200$ GeV, the rates due to both production cross sections decrease with $t_\beta$, the rate originating from the production via gluon fusion reaches a minimum in the $m_h^{alt}$ scenario, increasing at low values of $t_\beta$ in agreement with our discussion in Sec. III C.

Our inclusive interpretation of the heavy Higgs boson search is denoted by dashed black lines in Fig. 10. We also show the model-independent 95% C.L. upper bounds, provided explicitly in Ref. [36], as black solid lines. Observe that the slopes of the solid and dashed lines are very similar, implying that the model-independent bounds correspond approximately to the same inclusive production rate in both scenarios. Note the bound on $t_\beta$ we obtain in the

![Fig. 10](attachment:fig10.png)

FIG. 10 (color online). Comparison of exclusion limits obtained via the model-independent analysis and our inclusive interpretation of the limits for the $m_h^{mod_-+}$ scenario, with $\mu = 200$ GeV. The dots represent values of $t_\beta$ in units of 1, where values are labeled in blue or red corresponding to the $m_h^{mod_-+}$ scenario, with $\mu = 200$ GeV, and $m_h^{alt}$ scenario, with $\mu = m_Q$, respectively.
scenario, with $\mu = 200$ GeV, from the model-independent bounds is within one unit of the bound presented by CMS by a more sophisticated likelihood method.

The $t_\beta$ limit for a given $m_A$ in a different MSSM model corresponds roughly to the value where the inclusive production rate exceeds the upper limit in the $m_A^{\mathrm{mod+}}$ scenario, with $\mu = 200$ GeV. Since the sensitivity of the LHC in the gluon fusion and $b\bar{b}q\bar{q}$ channels is similar, we expect this to be a good approximation. Explicitly, in Fig. 10 we show the comparison of the bound in the $m_A^{\mathrm{alt}}$ scenario, with $\mu = m_Q$, using the inclusive production rate at the limiting value of $t_\beta$ presented by CMS in the $m_A^{\mathrm{mod+}}$ scenario, with $\mu = 200$ GeV, compared to the limit on the value of $t_\beta$ that could be interpreted from the model independent bound. Again, the difference using the two methods results in a difference for the $t_\beta$ limit of approximately one unit.

Using our inclusive interpretation, we can scale the limits from the $m_A^{\mathrm{mod+}}$ scenario, with $\mu = 200$ GeV, to any other scenario in a simple way in the region where $m_A = 200$–350 GeV. We then use the bounds from our inclusive interpretation to map out the direct search constraints on the $mA$-$t_\beta$ plane in each of our benchmarks, which in turn are compared against the constraints from precision measurements of the properties of the 125 GeV Higgs boson. We also use the inclusive production rate to analyze the future searches at the 14 TeV run of the LHC.

APPENDIX B: COMPARISON OF $hVV$ AND $h\gamma\gamma$ COUPLINGS

At low values of $\mu$ the charginos become light and therefore can lead to a modified diphoton coupling of the lightest $CP$-even Higgs boson. The contribution of top squarks and charginos to the amplitude in the diphoton channel is proportional to [17,48–51]

$$A_{h\gamma\gamma} = A_{h\gamma\gamma}^{\mathrm{SM}} + A_{h\gamma\gamma}^{\chi^\pm} + A_{h\gamma\gamma}^{\tilde{t}} + A_{h\gamma\gamma}^{\tilde{w}_{1,2}},$$

(B1)

where in this normalization $A_{h\gamma\gamma}^{\mathrm{SM}} = 6.5$ represents the SM contribution, $b_{\chi^\pm} = 4/3$, $b_{\tilde{t}} = 4/9$, and $m_{\tilde{w}_{1,2}}$ are the top squark mass eigenvalues. The parameters $m_t$ and $X_t$ are running mass parameters at the scale of the top squark masses in the $\overline{\text{MS}}$ scheme. For the large values of $X_t$ present in the $m_A^{\mathrm{alt}}$ scenario, the top squark contribution is small and positive. The chargino contribution is also small and becomes relevant only for small values of $\mu$ and of $t_\beta$. In the $m_A^{\mathrm{mod+}}$ scenario, for $\mu = 200$ GeV, the top squark contribution is even smaller, since $X_t^2$ is close to the sum of the squares of the top squark masses. In general, the supersymmetric loop corrections lead to a contribution of the order of a few percent of the SM one. Hence, the main deviation of the $\text{BR}(h \to \gamma\gamma)$ and $\text{BR}(h \toVV)$ in this region of parameters is mostly governed by the increase of the width of the lightest $CP$-even Higgs decay into bottom quarks and tau leptons at low values of $m_A$. Note that the contribution from top squarks to gluon fusion is approximately a factor of 3 larger than their contribution to the diphoton coupling [50–52]. However, the leading SM contribution has the opposite sign in this

![FIG. 11 (color online). Deviation of the signal strengths with respect to the SM values for the lightest Higgs boson decaying into two photons and two massive gauge bosons.](035003-21)
case, and hence, the gluon fusion rate is reduced from the SM expectation in the scenarios we consider, again at the few percent level.

In order to quantify these effects, in Fig. 11(a) we show contour plots of $\sigma \times \text{BR}(h \rightarrow \gamma\gamma)$ and $\sigma \times \text{BR}(h \rightarrow VV)$ normalized the SM values in the $m_h^\text{mod}$- and $m_h^\text{alt}$-scenarios for low values of $\mu$, for which no alignment condition is present. This choice of $\mu$ maximizes the differences between these channels. As can be seen, the overall behavior of these channels is the same, although the precise contour lines at low values of $t_\beta$ for which a particular deviation with respect to the SM value takes place is shifted by a few tens of GeV for $m_A < 350$ GeV for low values of $\mu$. No significant difference is present for larger values of $\mu$, as can be seen from Fig. 11(b). The peculiar behavior of the contour lines at low values of $t_\beta$ in the $m_h^\text{alt}$ scenario is induced by the variation of the gluon fusion cross section, which becomes more suppressed as the top squarks become heavier.

In this paper, in order to study the properties of the lightest $CP$-even Higgs bosons we shall concentrate on the BR$(h \rightarrow VV)$, but as shown in Fig. 11, similar conclusions would be obtained by the study of BR$(h \rightarrow \gamma\gamma)$ in this region of parameters.
