Scrutinizing the alignment limit in two-Higgs-doublet models.

II. \( m_H = 125 \) GeV

(Received 1 December 2015; published 29 February 2016)

In the alignment limit of a multidoublet Higgs sector, one of the Higgs mass eigenstates aligns in field space with the direction of the scalar field vacuum expectation values, and its couplings approach those of the Standard Model (SM) Higgs boson. We consider CP-conserving two-Higgs-doublet models (2HDMs) of type I and type II near the alignment limit in which the heavier of the two CP-even Higgs bosons, \( H \), is the SM-like state observed with a mass of 125 GeV, and the couplings of \( H \) to gauge bosons approach those of the SM. We review the theoretical structure and analyze the phenomenological implications of this particular realization of the alignment limit, where decoupling of the extra states cannot occur given that the lighter CP-even state \( h \) must, by definition, have a mass below 125 GeV. For the numerical analysis, we perform scans of the 2HDM parameter space employing the software packages 2HDMC and Lilith, taking into account all relevant pre-LHC constraints, constraints from the measurements of the 125 GeV Higgs signal at the LHC, as well as the most recent limits coming from searches for other Higgs-like states. Implications for Run 2 at the LHC, including expectations for observing the other scalar states, are also discussed.

DOI: 10.1103/PhysRevD.93.035027

I. INTRODUCTION

While the Higgs boson measurements at Run 1 of the LHC [1–3] (see also [4,5]) show no deviations from Standard Model (SM) expectations, conceptually there is no reason why the Higgs sector should be minimal. Indeed a nonminimal Higgs sector is theoretically very attractive and, if confirmed, would shine a new light on the dynamics of electroweak symmetry breaking. The challenge for Run 2 of the LHC, and other future collider programs, is to determine whether the observed state with mass 125 GeV is the SM Higgs boson, or whether it is part of a nonminimal Higgs sector of a more fundamental theory.

In models with a multidoublet Higgs sector such as the two-Higgs-doublet model [6,7] (2HDM), which is the focus of our study, a special situation arises when one of the Higgs mass eigenstates is approximately aligned in field space with the direction of the scalar field vacuum expectation values (vevs). This motivates the introduction of the Higgs basis, in which the scalar vev resides entirely in one linear combination of scalar fields. In the approach to the so-called alignment limit,\(^1\); the \( W^\pm \) and \( Z \) gauge bosons dominantly acquire their masses from the Higgs doublet of the Higgs basis with the nonzero vev, and the coupling of that Higgs boson to \( W^+W^- \) (and \( ZZ \)) tends toward its SM value, \( C_V \to 1 \).\(^2\) Of course, for consistency with the LHC measurements, this Higgs boson must then be identified with the observed SM-like state at 125 GeV.

In a recent paper [15], we provided a comprehensive study of the alignment limit in the context of CP-conserving 2HDMs of type I and type II, assuming that the observed 125 GeV state is the lighter of the two CP-even Higgs bosons, \( h \), in these models. Whereas alignment is automatically attained in the decoupling limit in the case of \( m_h = 125 \) GeV when the additional Higgs states \( H, A, H^\pm \) are very heavy, it can also occur when the additional Higgs states are

\(^1\)Aspects of the alignment limit were first emphasized in [8] and investigated further in [9–14].

\(^2\)We use the notation of coupling scale factors, or reduced couplings, employed in [4]: \( C_V (V = W, Z) \) for the coupling to gauge bosons, \( C_{U,D} \) for the couplings to up-type and down-type fermions and \( C_{\gamma,\phi} \) for the loop-induced couplings to photons and gluons.
light, i.e. alignment without decoupling [8]. The purpose of [15] was to investigate the phenomenological consequences of alignment without decoupling in the $m_h = 125$ GeV scenario and contrast the resulting phenomenology to the case of decoupling. In this paper, we now focus on the equally interesting but much less studied possibility that the observed 125 GeV state is the heavier $H$ of the two $CP$-even Higgs bosons of the 2HDM. In this case, alignment is always attained without decoupling, since by definition $h$ is lighter than $H$. Furthermore, the masses of the $CP$-odd Higgs boson $A$ and the charged Higgs boson $H^\pm$ are limited by the requirements of stability, perturbativity and electroweak precision measurements. The alignment limit in the $m_H = 125$ GeV scenario therefore offers a very specific phenomenology that is worth contrasting to that of the $m_h = 125$ GeV scenario.

The paper is organized as follows. In Sec. II we elaborate on theoretical considerations that are specific to the alignment limit in the case of $m_H = 125$ GeV. The numerical results of our study are presented in Sec. III. Two aspects are considered in detail: the precision measurements of the couplings and signal strengths of the SM-like Higgs boson at 125 GeV, and the ways to discover the additional Higgs states of the 2HDM when they are light. Section IV presents our conclusions. Throughout the paper we follow the notation and conventions used in [15]. The setup of the numerical analysis and the constraints applied also follow [15]. In addition, we consider the new CMS limit [16] for light neutral Higgs bosons with masses between 25 GeV and 80 GeV, produced in association with a pair of $b$ quarks and decaying into $\tau\tau$. Moreover, we take into account the CMS limits [17] on $gg \to A \to Zh$ with $Z \to e^+e^-$ and $h \to b\bar{b}$ or $\tau\tau$, which significantly constrain the scenario studied in this paper (but are much less relevant for the analysis of [15]). Details on the CMS $gg \to A \to Zh$ limits and their impact on the 2HDM parameter space are given in the Appendix.

**II. THEORETICAL CONSIDERATIONS**

In this section, we expand on the theoretical discussion in [15] (see also [18]), treating questions that are relevant specifically for a SM-like $H$ at 125 GeV. It is convenient to work in the Higgs basis [19,20], where the vev, $v = 2m_w/g \approx 246$ GeV, resides entirely in one of the two Higgs doublet fields,

$$\langle H^0_1 \rangle = v/\sqrt{2} \quad \text{and} \quad \langle H^0_2 \rangle = 0. \quad (1)$$

The scalar potential in the Higgs basis is

$$V = Y_1 H_1^* H_1 + Y_2 H_2^* H_2 + Y_3 [H_1^* H_2 + \text{H.c.}]$$

$$+ \frac{1}{2} Z_1 (H_1^* H_1)^2 + \frac{1}{2} Z_2 (H_2^* H_2)^2 + Z_3 (H_1^* H_1)(H_2^* H_2)$$

$$+ Z_4 (H_1^* H_2)(H_2^* H_1) + \left\{ \frac{1}{2} Z_5 (H_1^* H_1)^2 + Z_6 (H_1^* H_1) \right\} + Z_7 (H_2^* H_2)(H_1^* H_1) + \text{H.c.} \}, \quad (2)$$

where $Y_1 = -\frac{1}{2} Z_1 v^2$ and $Y_3 = -\frac{1}{2} Z_6 v^2$ at the scalar potential minimum. For simplicity, we assume that the field $H_2$ can be rephased such that the potentially complex parameters $Z_5$, $Z_6$ and $Z_7$ are real, in which case the scalar potential and Higgs vacuum are $CP$-conserving. Henceforth, we will always adopt such a “real basis,”\(^3\) In order to preserve perturbativity and tree-level unitarity [21–26], the dimensionless couplings $Z_i$ cannot be taken arbitrary large. Generically, the $Z_i$ are $O(1)$ constants, although it is possible for some of the $Z_i$ to be as large as $\sim 10$ without violating any low-energy constraints.\(^4\)

Under the assumption of a $CP$-conserving Higgs sector, the Higgs mass spectrum is exactly determined. The squared masses of the charged Higgs and $CP$-odd Higgs bosons are given by

$$m^2_{H^\pm} = Y_2 + \frac{1}{2} Z_3 v^2, \quad (3)$$

$$m^2_A = m^2_{H^\pm} + \frac{1}{2} (Z_4 - Z_5) v^2, \quad (4)$$

and the two $CP$-even squared masses are obtained by diagonalizing the $CP$-even Higgs squared-mass matrix,

$$M^2_H = \begin{pmatrix} Z_4 v^2 & Z_6 v^2 \\ Z_6 v^2 & m^2_A + Z_5 v^2 \end{pmatrix}. \quad (5)$$

The physical mass eigenstates are

$$H = (\sqrt{2}\text{Re}H_1^0 - v) c_{\beta - \alpha} - \sqrt{2}\text{Re}H_2^0 s_{\beta - \alpha}, \quad (6)$$

$$h = (\sqrt{2}\text{Re}H_1^0 - v) s_{\beta - \alpha} + \sqrt{2}\text{Re}H_2^0 c_{\beta - \alpha}. \quad (7)$$

where $m_h \leq m_H$. In Eqs. (6) and (7), the $CP$-even Higgs mixing angle in the Higgs basis is denoted by $\alpha - \beta$ and the notation $c_{\beta - \alpha} \equiv \cos(\beta - \alpha)$ and $s_{\beta - \alpha} \equiv \sin(\beta - \alpha)$ is

\(^3\)No rephasing of $H_1$ is permitted since by assumption the vev $v$ is real and positive.

\(^4\)Taking the $Z_i$ significantly larger than $O(1)$ will lead to Landau poles at an energy scale below the Planck scale [27–30]. However, we shall take an agnostic view in our scans by treating the 2HDM as an effective low-energy theory with no assumptions on its behavior at higher energies.
the following exact expressions:

\[
m^2_{H, h} = \frac{1}{2} \left[ m_A^2 + (Z_5 + Z_4) v^2 \pm \sqrt{m_A^2 + (Z_5 - Z_4) v^2} + 4Z_6^2 v^4 \right].
\]  

(8)

In light of Eq. (1), if \( \sqrt{2}ReH^0_1 - v \) were a mass eigenstate, then its tree-level couplings to SM particles and its self-couplings would be precisely those of the SM Higgs boson. That is, if one of the neutral CP-even Higgs mass eigenstates is approximately aligned in field space with the direction of the vev (the so-called alignment limit), then the couplings of this Higgs boson are SM-like. In [15], we examined the case of a SM-like \( h \), where alignment can be achieved in two ways. First, in the decoupling limit of the 2HDM with \( m_A \gg v \), the mixing of states in Eq. (5) is automatically negligible. Second, alignment without decoupling occurs if \( |Z_6|^2 \ll Z_1 v^2 \ll m_A^2 + Z_5 v^2 \). In both cases, \( h = \sqrt{2}ReH^0_1 - v \), corresponding to \( |c_{\beta - \alpha}| \ll 1 \).

In this paper we consider the case in which the heavier of the two CP-even neutral scalars \( H \) is identified as the SM-like Higgs boson with a mass of 125 GeV. Equations (6) and (7) them imply that \( H = \sqrt{2}ReH^0_1 - v \), corresponding to \( |s_{\beta - \alpha}| \ll 1 \). A SM-like \( H \) can only be achieved if

\[
|Z_6|^2 \ll |m_A^2 + (Z_5 - Z_4) v^2|,
\]

(9)

in which case the CP-even Higgs squared masses are given by

\[
m^2_H = Z_1 v^2 + \frac{Z_6^2 v^4}{|m_A^2 + (Z_5 - Z_4) v^2|} + \mathcal{O}(Z_6^2),
\]

(11)

\[
m^2_h = m_A^2 + Z_5 v^2 - \frac{Z_6^2 v^4}{|m_A^2 + (Z_5 - Z_4) v^2|} + \mathcal{O}(Z_6^2),
\]

(12)

in the approach to the alignment limit. In contrast to the case of a SM-like \( h \), there is no analog of the decoupling limit in which \( H \) is SM-like since \( h \) is necessarily lighter than \( H \), and the masses of \( H^\pm \) and \( A \) are typically of \( \mathcal{O}(v) \) in light of Eqs. (4) and (9).

The physical masses of the neutral scalars are related by the following exact expressions:

\[
Z_1 v^2 = m_H^2 s_{\beta - \alpha} + m_h^2 c_{\beta - \alpha},
\]

(13)

\[
Z_6 v^2 = (m_H^2 - m_h^2) s_{\beta - \alpha} c_{\beta - \alpha},
\]

(14)

\[
Z_5 v^2 = m_H^2 s_{\beta - \alpha} + m_h^2 c_{\beta - \alpha} - m_A^2.
\]

(15)

Using Eqs. (4) and (15), it also follows that

\[
Z_4 v^2 = m_H^2 s_{\beta - \alpha} + m_h^2 c_{\beta - \alpha} + m_A^2 - 2m_{H^\pm}^2.
\]

(16)

These equations exhibit all the features discussed above. In the exact alignment limit where \( H \) is identified as the SM Higgs boson and \( s_{\beta - \alpha} = 0 \), we see that \( Z_6 = 0 \), \( m_H^2 = m_A^2 + Z_5 v^2 \), \( m_h^2 = Z_7 v^2 \) and the inequalities of Eqs. (9) and (10) are satisfied. Indeed, all Higgs boson masses are of \( \mathcal{O}(v) \) in this limit. In contrast, if \( Z_6 = 0 \) is satisfied by taking \( c_{\beta - \alpha} = 0 \), it is evident that it is \( h \) that is SM-like.

The consequences of Eqs. (13)–(15) obtained in [15] were written in a form that was convenient for the case in which \( h \) is the SM-like Higgs boson, i.e. where \( |c_{\beta - \alpha}| \ll 1 \). In the case where \( H \) is the SM-like Higgs boson, i.e. \( |s_{\beta - \alpha}| \ll 1 \), it is more useful to rewrite the expressions obtained from Eqs. (13)–(15) as follows:

\[
m_H^2 = \left( Z_1 - Z_6 \frac{s_{\beta - \alpha}}{c_{\beta - \alpha}} \right) v^2, \]

(17)

\[
m_h^2 = m_A^2 + \left( Z_5 + Z_6 \frac{s_{\beta - \alpha}}{c_{\beta - \alpha}} \right) v^2.
\]

(18)

Note that Eqs. (13) and (14) imply that

\[
Z_6 s_{\beta - \alpha} c_{\beta - \alpha} \leq 0,
\]

(19)

\[
|Z_6|^2 v^2 = \sqrt{(m_H^2 - Z_1 v^2)(Z_1 v^2 - m_h^2)}.
\]

(20)

One can also derive expressions for \( c_{\beta - \alpha} \) and \( s_{\beta - \alpha} \) directly from Eqs. (13) and (14). In light of Eq. (19), the sign of the product \( s_{\beta - \alpha} c_{\beta - \alpha} \) is fixed by the sign of \( Z_6 \). However, since \( \beta - \alpha \) is defined only modulo \( \pi \), we are free to choose a convention where either \( c_{\beta - \alpha} \) or \( s_{\beta - \alpha} \) is always non-negative. A convenient choice of convention is dictated by the form of the couplings of the neutral CP-even Higgs bosons to \( VV \) (where \( VV = W^+ W^- \) or \( ZZ \)). Denoting the \( \phi VV \) couplings \( \phi = h, H \) normalized to the corresponding coupling of \( VV \) to the SM Higgs boson by \( C_V^\phi \), it follows that [6,7]

\[
C_V^h = s_{\beta - \alpha}, \quad C_V^H = c_{\beta - \alpha},
\]

(21)

as shown in Table I.

Since \( |s_{\beta - \alpha}| \ll 1 \) for a SM-like \( H \), the value of \( |c_{\beta - \alpha}| \) must be close to 1. In order to be consistent with the standard presentation of the SM Higgs Lagrangian, we shall choose a convention where \( c_{\beta - \alpha} \) is non-negative (so that \( C_V^H \to +1 \) in the alignment limit). In this convention,
now add the most general Higgs-fermion Yukawa scalar state beyond \( m_H \) which would flip the signs of \( s \), \( mA < m_H \) \[ cf. Eq. (25) \]. Similarly, if the conditions of Eq. (27) are satisfied, then \( \sin(\beta - \alpha) \), \( \sin(\beta - \alpha) \) are large and negative and \( Z_4 + Z_5 \) is large and negative and \( |Z_5| \lesssim O(1) \) , \( Z_4 + Z_5 \) is large and negative and \( |Z_5| \lesssim O(1) \) , \( m_A < m_H \) if \( Z_5 v^2 > -(m_H^2 - m_h^2) c_{\beta - \alpha}^2 \) \[ cf. Eq. (25) \]. Similarly, if the conditions of Eq. (27) are satisfied, then \( m_A < m_H \) if \( Z_5 v^2 > -(m_H^2 - m_h^2) c_{\beta - \alpha}^2 \) \[ cf. Eq. (24) \].

So far, the above discussion is applicable to the scalar sector of the most general \( CP \)-conserving 2HDM. If we now add the most general Higgs-fermion Yukawa couplings, we encounter tree-level Higgs-mediated flavor-changing neutral currents (FCNCs) that are too large and thus in conflict with experimental data \[32,33\]. It is well known that these FCNCs can be eliminated by introducing a new basis of scalar fields \( \{ \Phi_1, \Phi_2 \} \), and a \( Z_2 \) discrete symmetry, \( \Phi_1 \rightarrow + \Phi_1 \) and \( \Phi_2 \rightarrow - \Phi_2 \) under which the dimension-four terms of the Higgs scalar potential are invariant. This new basis of scalar fields (in which the \( Z_2 \) symmetry is manifest) is designated as the \( Z_2 \) basis, and is given in terms of the Higgs basis fields by \( ^5 \)

\[ \Phi_1 \equiv H_1 c_\beta - H_2 s_\beta, \quad \Phi_2 \equiv s_\beta H_1 + c_\beta H_2, \]  

where

\[ ^5 \] The translation between the Higgs and \( Z_2 \) bases is discussed in detail in \[8,15,18,20\].
and $\langle \Phi^0 \rangle = v_i$ ($i = 1, 2$). The $Z_2$ symmetry is then extended to the Higgs-fermion Yukawa couplings such that two of the four Higgs-quark Yukawa interaction terms (and their Hermitian conjugates) vanish (and similarly for the Higgs couplings to leptons). There are a number of ways to accomplish this. The type I model is defined by taking all right-handed fermion fields to be odd under the $Z_2$ symmetry in the Higgs-fermion interactions, whereas in type II Higgs-fermion interactions, only the up-type right-handed fermion field is odd under the $Z_2$ symmetry. The $Z_2$ symmetry guarantees that the neutral Higgs-fermion couplings are diagonal in flavor space unless $\tan \beta$ is very small (which is excluded by constraints related to stability, unitarity and perturbativity, in particular the requirement of perturbativity of the top Yukawa coupling). Thus, $C^H_1 \to 1$ in the alignment limit. In type II models we arrive at a similar conclusion for the up-type fermion-Higgs Yukawa coupling, namely $C^H_2 \to 1$ in the alignment limit. However, $C^H_D \to 1$ only when $|s_{\beta \rightarrow c_{\beta}} \tan \beta| \ll 1$, which means that if $\tan \beta \gg 1$ then the approach to the alignment limit, $C^H_D \to 1$, is delayed.

In the $Z_2$ basis of scalar fields defined in Eq. (29), $\alpha$ is the $CP$-even Higgs mixing angle, which is defined modulo $\pi$, and $\tan \beta = v_2/v_1$ is the ratio of neutral Higgs vevs [cf. Eq. (30)]. In a convention in which $c_{\beta \rightarrow a}$ is non-negative, the sign of $s_{\beta \rightarrow a}$ is determined by

$$c_{\beta} \equiv \cos \beta = v_1/v, \quad s_{\beta} \equiv \sin \beta = v_2/v, \quad (30)$$

Eq. (19). However, in introducing the $Z_2$ basis, there is freedom to impose an additional sign convention such that the vevs $v_1$ and $v_2$ are non-negative. That is, we assume henceforth that $\tan \beta$ is non-negative, or equivalently,

$$0 \leq \beta \leq \frac{\pi}{2} \pi. \quad (33)$$

For non-negative $\tan \beta$ and $c_{\beta \rightarrow a}$, it is clear from Eqs. (31) and (32) that the sign of $s_{\beta \rightarrow a}$ is physically relevant. In light of Eq. (22), it also follows that the sign of $Z_\alpha$ is now meaningful. These observations can be understood in another way as follows. Since $\tan \beta$ is assumed to be non-negative, one is no longer permitted to perform field redefinitions that change the relative sign of $\Phi_1$ and $\Phi_2$. Using Eq. (29), it then follows that one is no longer permitted to perform a redefinition of the Higgs basis field $H_2 \rightarrow -H_2$. But, we previously used such a field redefinition to conclude that the signs of $Z_\alpha$ and $s_{\beta \rightarrow a}$ are unphysical [see the text following Eq. (23)]. This is no longer possible once we fix a convention where $\tan \beta$ is non-negative.

Another common choice in the literature is to take $-\frac{1}{2} \pi \leq \alpha \leq \frac{1}{2} \pi$ along with Eq. (33), in which case parameter regimes exist in which $c_{\beta \rightarrow a}$ and/or $s_{\beta \rightarrow a}$ can take on either sign. It is a simple matter to translate among the various conventions. For example, given any 2HDM parameter point $(\alpha, \beta)$ with $-\frac{1}{2} \pi \leq \alpha \leq \frac{1}{2} \pi$ and $0 \leq \beta \leq \frac{1}{2} \pi$, one can compute the values of $s_{\beta \rightarrow a}$ and $c_{\beta \rightarrow a}$. Then, to convert to the convention of non-negative $c_{\beta \rightarrow a}$, one would simply replace

$$s_{\beta \rightarrow a}, c_{\beta \rightarrow a} \rightarrow (-s_{\beta \rightarrow a}, -c_{\beta \rightarrow a}) \quad (34)$$

if $c_{\beta \rightarrow a}$ is initially negative. Only the relative sign of $s_{\beta \rightarrow a}$ and $c_{\beta \rightarrow a}$ is physical for a given sign choice of $Z_\alpha$ in light of Eq. (19).

Let us now examine the number of parameters that govern the $CP$-conserving 2HDM of types I and II. In order to ensure the absence of tree-level Higgs-mediated FCNCs, it is sufficient to impose the $Z_2$ discrete symmetry introduced above on all dimension-four terms of the Higgs Lagrangian. Thus, we are free to include terms in the Higgs Lagrangian that softly break the symmetry. There exists precisely one term of this type, namely the following dimension-two term that can be added to the scalar potential in the $Z_2$ basis,

$$V_{\text{soft}} = -m_{H_1}^2 \Phi_1^\dagger \Phi_2 + \text{H.c.} \quad (35)$$

The squared-mass parameter $m_{H_1}^2$ is related to the Higgs basis parameters and the angle $\beta$ via
Note that if \( \sin 2\beta = 0 \), then the \( Z_2 \) basis and the Higgs basis coincide\(^7\) [cf. Eqs. (24) and (25) of [15]] and \( Z_6 = Z_7 = 0 \). The latter implies that \( m_{12}^2 = 0 \) in light of Eq. (36). That is, if \( \beta = 0 \) or \( \frac{1}{2} \pi \) then the \( Z_2 \) discrete symmetry, under which the Higgs basis fields \( H_1 \rightarrow +H_1 \) and \( H_2 \rightarrow -H_2 \), is exact (and cannot be softly broken\(^8\)).

As an aside, we note that the so-called inert doublet model (IDM) [41–43] can be defined as a type I 2HDM with \( Z_6 = Z_7 = 0 \) [11], in which all fields (excepting \( H_2 \)) are even under the \( Z_2 \) discrete symmetry. In light of the above discussion, we see that the alignment limit is exact in the IDM and \( \sqrt{2}H_1^0 - v \) is identified as the SM Higgs boson, which can either be the lighter or the heavier of the two \( CP \)-even Higgs bosons, depending on whether the inequality given in Eq. (9) is satisfied. The phenomenology of the IDM has been treated in detail in [44–46], so we do not pursue this case further in this paper.

Henceforth, we assume that \( \sin 2\beta \neq 0 \). The eight free parameters of the \( CP \)-conserving, softly broken \( Z_2 \)-symmetric 2HDM are \( v, \alpha, \beta, m_h, m_H, m_A, m_{H^\pm} \) and \( m_{12}^2 \), where \( 0 < \beta < \frac{1}{2} \pi \) and \( |\beta - \alpha| \leq \frac{1}{2} \pi \). The same counting can be performed in the Higgs basis. Note that the imposition of the discrete \( Z_2 \) symmetry on the quartic terms of the scalar potential yields two relations among the \( Z_i \) as shown in [15,18]

\[
Z_2 v^2 = m_h^2(s_{\beta-\alpha} + 2c_{\beta-\alpha} \cot 2\beta)^2 + m_H^2(c_{\beta-\alpha} - 2s_{\beta-\alpha} \cot 2\beta)^2 - 4\tilde{m}^2 \cot^2 2\beta, \tag{41}
\]

\[
Z_3 v^2 = m_h^2 s_{\beta-\alpha}^2 + m_H^2 c_{\beta-\alpha}^2 + 2(m_h^2 - m_H^2) c_{\beta-\alpha} s_{\beta-\alpha} \cot 2\beta + 2(m_{H^\pm}^2 - \tilde{m}^2) \tag{42}
\]

\[
Z_7 v^2 = 2(m_h^2 s_{\beta-\alpha}^2 + m_H^2 c_{\beta-\alpha}^2 - \tilde{m}^2) \cot 2\beta + (m_h^2 - m_H^2)s_{\beta-\alpha}c_{\beta-\alpha}. \tag{43}
\]

Note that the following conditions are necessary (although not sufficient) to guarantee that the scalar potential in the Higgs basis is bounded from below [8,41];

\[
Z_1 > 0, \quad Z_2 > 0, \quad Z_3 > -\sqrt{Z_1 Z_2}. \tag{44}
\]

The condition \( Z_1 > 0 \) is automatically satisfied in light of Eq. (13). The constraints on \( Z_3 \) and \( Z_4 \) imposed by Eq. (44) place mild constraints on the Higgs parameters employed in our numerical scans.

\(^7\)Strictly speaking, if \( \beta = \frac{1}{2} \pi \) then we need to interchange the Higgs basis fields \( H_1 \) and \( H_2 \) to be consistent with the definition of the Higgs basis specified in Eq. (1).

\(^8\)Due to the potential minimum condition \( Y_1 = -\frac{1}{2} Z_6 v^2 \), it follows that \( Z_6 = Z_7 = 0 \) in the Higgs basis is sufficient to guarantee that the entire scalar potential respects the \( Z_2 \) symmetry.

Finally, we examine the trilinear Higgs self-couplings, focusing on those involving the \( H \). Explicit expressions for these couplings in terms of the \( Z_i \) and \( \beta - \alpha \) have been given in [15]. The corresponding three-Higgs vertex Feynman rules (including the corresponding symmetry factor for identical particles but excluding an overall factor of \( i \)) are given by

\[
g_{HHH} = -3v[2Z_1 c_{\beta-\alpha} + Z_3 s_{\beta-\alpha}^2] - 3Z_6 s_{\beta-\alpha} c_{\beta-\alpha} - Z_7 s_{\beta-\alpha}^3, \tag{45}
\]

\(^9\)For \( \beta = \frac{1}{2} \pi \), Eq. (38) implies that \( Z_6 = Z_7 \), in which case \( Z_3 \) must be considered as an independent quantity.

\(^{10}\)The Higgs-basis parameter \( Z_3 \) only appears in the quartic Higgs couplings, which we do not address in this paper. We only provide Eq. (41) for the sake of completeness.
SCRUTINIZING THE ... II. \( m_H = 125 \) GeV

\[ g_{Hhh} = -3v \left[ Z_1 c_{\beta - \alpha} s_{\beta - \alpha}^2 + Z_3 45 c_{\beta - \alpha} \left( \frac{1}{3} - s_{\beta - \alpha}^2 \right) \right. \]
\[ \left. - Z_6 s_{\beta - \alpha} (1 - 3 c_{\beta - \alpha}^2) - Z_7 c_{\beta - \alpha} s_{\beta - \alpha} \right] . \]  

(46)

\[ g_{HAA} = -v [(Z_3 + Z_4 - Z_5) c_{\beta - \alpha} - Z_7 s_{\beta - \alpha}] , \]

(47)

\[ g_{HHH+H} = -v [Z_3 c_{\beta - \alpha} - Z_7 s_{\beta - \alpha}] , \]

(48)

where we have introduced the notation

\[ Z_{345} \equiv Z_3 + Z_4 + Z_5 . \]  

(49)

In the alignment limit \(| s_{\beta - \alpha} | \to 0 \), Eqs. (17) and (45) yield

\[ g_{HHH} = g_{HHH}^{SM} \left[ 1 - \frac{2 Z_6}{Z_1} s_{\beta - \alpha} + \left( \frac{Z_3 45 - \frac{3}{2}}{Z_1^2} s_{\beta - \alpha} \right) \right. \]
\[ \left. + O(s_{\beta - \alpha}^3) \right] . \]  

(50)

where the self-coupling of the SM Higgs boson is given by

\[ g_{HHH}^{SM} = -\frac{3 m_H^2}{v} = -3v \left( Z_4 - Z_6 s_{\beta - \alpha} / c_{\beta - \alpha} \right) . \]  

(51)

It is convenient to make use of Eq. (22) [in a convention where \( c_{\beta - \alpha} \geq 0 \)] to write

\[ s_{\beta - \alpha} = -\eta Z_6 , \]  

(52)

where

\[ \eta = \frac{v^2}{\sqrt{(m_H^2 - m_h^2)(Z_1 v^2 - m_h^2)}} \]  

(53)

is a positive \( O(1) \) parameter. In the approach to the alignment limit, Eqs. (11) and (12) yield

\[ \eta = \frac{v^2}{m_A^2 + (Z_5 - Z_1) v^2} + O(Z_6^2) . \]  

(54)

Inserting Eq. (52) in Eq. (50) yields

\[ g_{HHH} = g_{HHH}^{SM} \left[ 1 + \left( \frac{Z_{345} - \frac{3}{2} Z_1}{Z_1^2} \right) \eta^2 + 2\eta \right] \frac{Z_6^2}{Z_1} \]
\[ + O(Z_6^3) \right] . \]  

(55)

In light of Eqs. (38) and (49), the parameter \( Z_{345} \) depends on \( Z_6 \). We can therefore rewrite Eq. (55) as

\[ g_{HHH}^{SM} = g_{HHH}^{SM} \left[ 1 + \left( \frac{Z_7 \tan 2\beta - \frac{1}{2} Z_1}{Z_1} \right) \eta^2 + 2\eta \right] \frac{Z_6^2}{Z_1} \]
\[ + (2 \cot 2\beta - \tan 2\beta) \eta^2 \frac{Z_6^2}{Z_1} + O(Z_6^3) \right] , \]  

(56)

where the term designated by \( O(Z_6^3) \) contains no potential enhancements in the limit of \( s_{2\beta} \to 0 \) or \( c_{2\beta} \to 0 \). The \( HHH \) coupling can thus be either suppressed or enhanced with respect to the SM. For example \( g_{HHH} > g_{HHH}^{SM} \) is possible in two cases. If \( \tan \beta \sim 1 \), then one must satisfy \( (Z_1 - Z_6) \eta \tan 2\beta \gtrsim \frac{1}{2} Z_1 \eta - 2 \). Alternatively, if \( \tan \beta \gg 1 \), then one must satisfy \( Z_6 \eta \cot 2\beta \gtrsim \frac{1}{2} Z_1 \eta - 1 \). In both cases, the \( HHH \) coupling is enhanced even when \( |Z_6| \) is significantly smaller than \( 1 \).

Next, consider the \( Hhh \) and \( HAA \) couplings given in Eqs. (46) and (47). Both these couplings approach nonzero values in the alignment limit \((s_{\beta - \alpha} \to 0)\),

\[ g_{Hhh} = -v Z_{345} + O(s_{\beta - \alpha}) , \]  

(57)

\[ g_{HAA} = -v (Z_{345} - 2Z_5) + O(s_{\beta - \alpha}) . \]  

(58)

One can now eliminate \( Z_{345} \) in favor of \( Z_6 \) as before. After employing Eq. (17), we end up with

\[ g_{Hhh} = -\frac{1}{v} \left( m_H^2 - (Z_6 - Z_1) v^2 \tan 2\beta \right. \]
\[ \left. + 2Z_6 v^2 \cot 2\beta + O(Z_6) \right] , \]  

(59)

where the term designated by \( O(Z_6) \) contains no potential enhancements in the limit of \( s_{2\beta} \to 0 \) or \( c_{2\beta} \to 0 \).

Last but not least, it is noteworthy that

\[ g_{HHH-H} = -v Z_3 + O(s_{\beta - \alpha}) \]  

(60)

approaches a finite nonzero value in the alignment limit. This is relevant for the analysis of the loop-induced process \( H \to \gamma \gamma \), which has a contribution that is mediated by an \( H^\pm \) loop. Recall that the charged Higgs mass is given by Eq. (25), which cannot be much heavier than \( O(v) \). Hence, the charged Higgs loop is parametrically of the same order as the corresponding SM loop contributions, thereby leading to a shift of the effective \( H\gamma \) coupling from its SM value. This is in stark contrast to the behavior of tree-level Higgs couplings, which approach their SM values in the alignment limit.

Although we expect \( m_{H^\pm} \lesssim O(v) \) over most of the 2HDM parameter space when \( H \) is a SM-like Higgs boson, there exists a parameter regime [cf. Eqs. (27) and (28)] in which \( m_{H^\pm} \gg m_H \). Indeed, a heavy charged Higgs mass is required in type II to avoid conflict with the observed rate
for \( b \to s \tau \) [47]. In light of Eqs. (3) and (4), suppose that \( Y_2 \ll Z_3 v^2 \) where \( Z_3 \) is large [say, of \( \mathcal{O}(10) \)] but still consistent with the unitarity bounds. In order to satisfy the inequality given in Eq. (9), \( Z_4 + Z_5 \) must be negative and its magnitude must be large (but not too large in order to satisfy the unitarity bounds). It then follows that \( m_{H^\pm}^2 = \frac{1}{2} Z_3 v^2 \), in which case Eq. (48) yields
\[
g_{HH^+H^-} = - \frac{2 m_{H^\pm}^2}{v} + \mathcal{O}(v^3),
\]
in the approach to the alignment limit.

One can also obtain Eq. (61) by expressing \( g_{HH^+H^-} \) in terms of the Higgs masses and the squared-mass parameter \( \bar{m}^2 \) defined in Eq. (39). Inserting Eqs. (42) and (43) into Eq. (48) yields [15,48]
\[
g_{HH^+H^-} = - \frac{1}{v} \left\{ \left( m_H^2 + 2 (m_{H^\pm}^2 - \bar{m}^2) \right) c_{\beta-a} \right. \]
\[
- 2 \cot 2\beta (m_H^2 - \bar{m}^2) s_{\beta-a} \left\} \right.,
\]
where \( m_H = 125 \text{ GeV} \). In the parameter regime where \( m_{H^\pm} \) is large [such that \( Y_2 \ll Z_3 v^2 \) as discussed above Eq. (61)], it follows from Eq. (39) that \( \bar{m}^2 \sim O(v^2) \).\(^{11}\) Thus, in the alignment limit with \( m_{H^\pm} \) large compared to \( v \), one again obtains the asymptotic result of Eq. (61).

We denote the one-loop \( H \to \gamma \gamma \) amplitude normalized to the corresponding SM value by \( C_{\gamma}^H \). The coupling given in Eq. (61) matches precisely the \( HH^+H^- \) interaction term of
\[
\mathcal{L}_{\text{int}} = - \frac{g_{m_i}^2}{2 m_{WW}} \bar{t}H + g_{m_H} W_{\mu}^+ W_{\mu}^- H - \frac{g_{m_{H^\pm}}^2}{m_{WW}} H^+ H^- H^-, \quad (64)
\]
given in Eq. (2.15) of [6]. Hence, we can immediately obtain an estimate for \( C_{\gamma}^H \) in the alignment limit by employing the asymptotic forms for the contributions to the \( H \to \gamma \gamma \) amplitude, \( F_i \) (corresponding to a particle in the loop with spin \( i = 0, \frac{1}{2}, 1 \)) given in Eq. (2.21) of [6],

\(^{11}\)If \( |\cot 2\beta| \gg 1 \), it is more convenient to invoke Eqs. (9) and (40) to conclude that \( \bar{m}^2 \sim O(v^2) \).

PHYSICAL REVIEW D 93, 035027 (2016)

\[
C_{\gamma}^H = \frac{F_0 + F_1 + 3 e_i^2 F_{1/2}}{F_1 + 3 e_i^2 F_{1/2}} = 0.94, \quad (65)
\]
where \( e_i = \frac{2}{3} \) is the charge of the top quark in units of \( e \), \( F_0 = -\frac{1}{4} \), \( F_{1/2} = -\frac{3}{4} \) and \( F_1 = 7.12 \). A more complete calculation taking into account finite-mass effects yields a very similar result, \( C_{\gamma}^H = 0.95 \). That is, the contribution of the charged Higgs loop asymptotically yields a 5% reduction in \( C_{\gamma}^H \).

In contrast, in the case of lighter charged Higgs boson masses (which are allowed in type I), the approximate form of the \( HH^+H^- \) coupling given in Eq. (61) and the asymptotic form for \( F_0 \) employed in Eq. (65) are no longer valid. In particular, in the approach to the alignment limit, \( g_{HH^+H^-} \propto -vZ_3 \). When \( Z_3 > 0 \) [as in Eq. (61) where \( Z_3 \sim 2 m_{H^\pm}^2 / v^2 \)], the charged Higgs loop interferes destructively with the \( W \) boson loop. However, for small values of \( m_{H^\pm} \), there exist regions of the 2HDM parameter space where \( Z_3 < 0 \) [consistent with the bounds given in Eq. (44)], which then yields an \( HH^+H^- \) coupling of the opposite sign. In this case, the charged Higgs boson loop interferes constructively with the \( W \) boson loop, thereby generating a value of \( C_{\gamma}^H > 1 \). Using Eq. (63), it follows that the sign flip of \( g_{HH^+H^-} \) occurs roughly when \( 2m_{12}^2 > 2m_{H^\pm}^2 + m_W^2 \). In practice, as we shall see in Sec. III, positive values of \( \bar{m}^2 \) do not exceed about (150 GeV)\(^2 \), which implies that a light charged Higgs boson with a mass of about \( m_{H^\pm} < 160 \text{ GeV} \) is required for \( C_{\gamma}^H > 1 \). The nondecoupling of the charged Higgs contribution and the possible sign flip in \( g_{HH^+H^-} \) was also addressed in Appendix B of [49].

III. NUMERICAL RESULTS

Let us now turn to the numerical scan of the 2HDM parameter space. The free parameters in our analysis are the four physical Higgs masses \( m_h, m_{H^\pm}, m_{H^\pm}, m_A \), the squared-mass parameter \( m_{12}^2 \), the ratio of the two Higgs vacuum expectation values \( \tan \beta \) and the mixing angle \( \alpha \) of the CP-even Higgs squared-mass matrix. Setting \( m_H \equiv 125.5 \text{ GeV} \),\(^{13}\) we allow the 2HDM parameters to vary in the following ranges:
\[
\alpha \in [-\pi/2, \pi/2], \quad \tan \beta \in [0.5, 60],
\]
\[
m_{12}^2 \in [-(2000 \text{ GeV})^2, \quad (2000 \text{ GeV})^2],
\]
\[
m_h \in [10 \text{ GeV}, 121.5 \text{ GeV}], \quad m_{H^\pm} \in [m_e, 2000 \text{ GeV}],
\]
\[
m_A \in [5 \text{ GeV}, 2000 \text{ GeV}],
\]

\(^{13}\)These asymptotic forms are valid when \( 4m_{H^\pm}^2 / m_{12}^2 \gg 1 \), where \( m_i \) is the mass of the particle in the loop. Nevertheless, these approximations work quite well even for the \( t \) quark and the \( W \) boson.

\(^{12}\)Having performed the parameter scans before the publication of [50] which reports a central value of the Higgs mass of 125.09 GeV, we use 125.5 GeV as the observed Higgs mass in this analysis.
where \(m^*\) is the lower bound on the charged Higgs mass in type I or type II. Note that, as in [15], the degenerate case \(m_b = m_H\) is not considered in this study. Instead, we require a 4 GeV mass splitting between \(h\) and \(H\) in order to avoid \(h\) contamination of the \(H\) signal. Since we are primarily interested in the near-alignment case, we allow at most a 1% deviation from \(m_b = m_H\). We note that although the scan was performed in terms of \(\alpha\) and \(\tan \beta\) as given in Eq. (66), we will present our results in the convention of \(c_{\beta-\alpha} \geq 0\). That means, given a point \((\alpha, \tan \beta)\) in our scan with \(c_{\beta-\alpha} < 0\), we convert to the positive \(c_{\beta-\alpha}\) convention by making the replacement \(\alpha \rightarrow \alpha + \pi [\text{see also the discussion around Eq. (34)]}\). Thus our alignment condition translates into \(c_{\beta-\alpha} \geq 0.99\) whereas \(s_{\beta-\alpha}\) can have either sign.

As in [15], the public tools used include 2HDMC [51] for computing couplings and decay widths and for testing theoretical constraints in the 2HDM, Lilith 1.1.2 [52] (with database version 15.04) for evaluating the Higgs signal strength constraints, and sуши-1.3.0 [53] and vBFNLO-2.6.3 [54] for computing production cross sections at the LHC. The setup of the analysis and the experimental constraints imposed are exactly the same as in [15], with three additions. First, we include the recent update of the bound on the charged Higgs mass in type II, \(m_{h^+} \geq 480\) GeV at 95\% C.L. [47], based on the observed rates for the weak radiative \(B\)-meson decay, \(B \rightarrow X_s \gamma\). Second, we take into account the new CMS result [17] on the search for a new heavy resonance decaying to a \(Z\) boson and a light resonance, followed by \(Z \rightarrow \ell^+ \ell^-\) and the light resonance decaying to \(b\bar{b}\) or \(\tau \tau\). In particular, the cross section upper limit for the \(\ell^+ \ell^- b\bar{b}\) final state in the plane of the masses of the two resonances, Fig. 5b of [17], puts a very severe constraint on \(gg \rightarrow A \rightarrow Z \ell \ell\) with \(Z \rightarrow \ell^+ \ell^-\) and \(h \rightarrow b\bar{b}\) in our study.\(^{14}\) This is in contrast to the \(m_b = 125\) GeV case studied in [15], where this limit is much less relevant. There are two reasons for the larger impact in the \(m_H \approx 125\) GeV, \(c_{\beta-\alpha} \geq 0.99\) scenarios studied here: first, the \(ZH\) coupling is proportional to \(c_{\beta-\alpha}\) and therefore \(\text{BR}(A \rightarrow Zh)\) is typically large; second, \(\text{BR}(h \rightarrow b\bar{b}) \approx 1\) since the \(h\) is always light. Finally, the CMS constraint [16] on neutral Higgs bosons with masses between 25 GeV and 80 GeV, produced in association with a pair of \(b\) quarks, followed by the decay into \(\tau \tau\), is also applied in our analysis. We find that this constraint eliminates a substantial part of the type II parameter space at large \(\tan \beta\). Unless otherwise stated, all parameter space points shown in the following satisfy all of the latest constraints. For more details on the numerical procedure, we refer the reader to [15].

A. Parameters

We start by illustrating the parameter space of the analysis. Figure 1 shows the relation between \(m_{h^+}, |s_{\beta-\alpha}|\) and \(\log_{10} |Z_\alpha|\).\(^{15}\) The expected correlation between the three

\(^{14}\)The corresponding ATLAS search for \(A \rightarrow Zh\) with \(Z \rightarrow \ell \ell\) and \(h \rightarrow b\bar{b}\) (or \(\tau \tau\)) [55] assumes a SM-like \(h\) with 125 GeV mass and thus does not apply here. (It would apply to \(A \rightarrow Zh\) in our study, but does not give any relevant constraint for this case).

\(^{15}\)In this and subsequent figures, we give 3d information on a 2d plot by means of a color code in the third dimension. To this end, we must choose a definite plotting order. Ordering the points from high to low values in the third dimension, as done for \(\log_{10} |Z_\alpha|\) in Fig. 1, means that the highest values are plotted first and lower and lower values are plotted on top of them. As a consequence, regions with low values may (partly) cover regions with high values. The opposite is of course true for the ordering from low to high values. To avoid a proliferation of plots, in each figure we show only one ordering, trying to choose the one that gives most information. The figures with inverted plotting order are available upon request.
parameters is clearly observed. In particular, larger values of \( m_h \) imply smaller \(|Z_6|\) for the same value of \( |s_{\beta-a}| \), and for each \( m_h \), \( \log_{10} |Z_6| \) can be as small as desired if \( |s_{\beta-a}| \) is allowed to be correspondingly small. Here, we show results down to \( |s_{\beta-a}| = 10^{-5} \); we have checked that this catches all the phenomenology of the scenarios under consideration. Because of the absence of a decoupling limit, \(|Z_6|\) does not exceed \( \sim 10^{-1.5} \) in our scan. This illustrates that in the scenario under consideration, alignment is solely controlled by the smallness of \(|Z_6|\). Note also that the region of \( m_A \leq \frac{1}{2} m_H \) requires subtle correlations among the 2HDM parameters to ensure that \( \text{BR}(H \to hh) \) is sufficiently small to be in agreement with the experimental constraints [56]. This explains the relatively low density of points in this region. On the other hand, the higher density of points seen in type II for \( m_h \in [80 \text{ GeV}, 90 \text{ GeV}] \) arises because light neutral states \( X = h, A \) with masses below 80 GeV are severely constrained by the CMS \( bbX \) with \( X \to \tau\tau \) search [16], while masses above 90 GeV are also constrained by the ATLAS [58] and CMS [59] searches for \( X \to \tau\tau \) decays in both the \( gg \to X \) and \( bbX \) production modes.

The relation between the three free Higgs masses, \( m_A \), \( m_{H^\pm} \) and \( m_h \) is shown in Fig. 2. The absence of a decoupling limit results in an upper bound on the \( CP \)-odd and charged Higgs masses, \( m_A, m_{H^\pm} \lesssim 630 \text{ GeV} \), which depends on the allowed values of \( c_{\beta-a} \). Indeed, without the \( c_{\beta-a} \geq 0.99 \) constraint that we imposed to focus on the alignment scenario, one would find instead \( m_A, m_{H^\pm} \lesssim 800 \text{ GeV} \), where the bound is saturated for \( s_{\beta-a} = 0.7 \) [49]. The characteristic correlation between \( m_A \) and \( m_{H^\pm} \) is a consequence of the precision electroweak measurements, primarily the \( T \) parameter [60]. In type II, a large part of the parameter space is excluded by weak radiative \( B \) meson decays for which agreement with observations sets a strong lower bound on the charged Higgs mass, \( m_{H^\pm} > 480 \text{ GeV} \) at 95\% C.L., which is practically independent of \( \tan\beta \) for \( \tan\beta > 2 \), and is even stronger for \( \tan\beta < 2 \) [47]. This constraint, in association with the distinctive \( m_A-m_{H^\pm} \) correlation, sets a bound on the \( CP \)-odd Higgs mass. We find that \( m_A \gtrsim 420 \text{ GeV} \), which rules out the region of \( m_A \leq \frac{1}{2} m_H \) in type II. We also note that this forces the \( CP \)-odd and charged Higgs states to be relatively close in mass.

In contrast to type II, the charged Higgs mass is much less impacted from flavor physics constraints [7,61] in type I. For \( m_{H^\pm} \lesssim 160 \text{ GeV} \), the \( CP \)-odd state can have any mass below 630 GeV in type I, as shown in the left panel in Fig. 2. Moreover, whereas \( m_h \leq \frac{1}{2} m_H \) can only be found for \( m_A, m_{H^\pm} \gtrsim 400 \text{ GeV} \) in type II, such a light \( h \) is possible for most of the allowed combinations of \( m_A \) and \( m_{H^\pm} \) in type I—with the notable exception of the light \( m_A \leq \frac{1}{2} m_H \) region, since LEP constraints imply that \( A \) and \( h \) cannot both have a mass below \( \frac{1}{2} m_H \) simultaneously [56]. However, there are narrow bands at the border of the allowed \( m_A \) vs \( m_{H^\pm} \) region that unambiguously lead to values of \( m_h \gtrsim 100 \text{ GeV} \). One such region is the blue band in the left panel of Fig. 2 with \( m_A \gtrsim 350 \text{ GeV} \) and \( m_{H^\pm} \lesssim 200 \text{ GeV} \). Such mass correlations may be used to predict or cross-check the validity of the scenario in the case that two or three extra Higgs states are discovered in the future. Finally, as discussed in [56], \( m_h \) values below about 60 GeV are only possible for \( \tan\beta \lesssim 2 \) in type II. Hence, if such a low mass \( h \) is observed and its properties require a high value of \( \tan\beta \), then the type II model would be eliminated.

---

\(^{16}\)The CMS analysis given in [16] considers only \( pp \to bbA \) production with \( A \to \tau\tau \). However, the same limit should also apply to \( pp \to bbh \) with \( h \to \tau\tau \); see e.g. [57].
B. Couplings

Let us now turn to the properties of the \( H \) in the (near-)alignment regime. Figure 3 shows the possible variation of the coupling of \( H \) to up-type fermions, \( C^H_U \equiv C^H_F \) in type I and \( C^H_U \) in type II. Deviations from unity ranging from \(-12\%\) to \(+8\%\) are possible in type I for \( |s_{\beta-\alpha}| \sim 0.14 \), while in type II the deviations range from \(-7\%\) to \(+20\%\). As expected, in both types \( C^H_U \) quickly approaches unity as \( |s_{\beta-\alpha}| \) decreases. It is interesting to note that, while \( C^H_U = \sin \alpha / \sin \beta \) in both type I and type II, the actual values that can be reached are different in the two models because of constraints involving the down-type coupling. The largest deviations occur for large \( h-A \) mass splitting, when \( m_h \) is below 60 GeV, while \( m_A \) is close to its upper bound. As discussed in \([56]\), \( \tan \beta \) is very close to 1 in this case. In type I, there is also another region with \( m_h < \frac{1}{2} m_H \) at larger values of \( \tan \beta \), although this is only achieved when \( |s_{\beta-\alpha}| \gtrsim 10^{-2} \). This is seen as the narrow banana-shaped red strip with \( C_F \approx 1-1.01 \) in the upper left panel of Fig. 3. Also noteworthy are the white gaps between the regions filled with valid scan points: these are caused by the CMS limits \([17]\) on \( A \rightarrow Zh \rightarrow \ell \ell b \bar{b} \) (and \( \ell \ell \tau \tau \)) and will appear in many of the subsequent figures. The impact of this limit is discussed in more detail in the Appendix.

The possible variation of the coupling to down-type fermions, \( C^D_U \), in type II is shown in Fig. 4. Let us first consider the left panel. As in the \( m_H = 125 \) GeV case, there are two solutions: one where \( C^H_U \), \( C^H_U \), and \( C^D_U \) all have the same sign (as is the case in the SM), and one where \( C^D_U \) has opposite sign relative to \( C^H_U \) and \( C^H_U \) \([48]\). In the normal (same) sign region, deviations from the predicted SM coupling in the range of roughly \(-30\%\) to \(+12\%\) are possible even for rather low \( |s_{\beta-\alpha}| \sim 5 \times 10^{-3} \), as long as the \( H \rightarrow hh \) decay mode is closed. If the \( H \rightarrow hh \) decay (which is constrained to \( \text{BR}(H \rightarrow hh) \lesssim 0.27 \) at 95\% C.L. by the fit to the 125 GeV signal strength measurements) contributes to the total width, then \( C^D_U \) is confined to the range \([0.83, 1.08]\) and quickly converges to unity as \( |s_{\beta-\alpha}| \) decreases. Note however that \( C^H_U \) is never exactly 1 unless \( |s_{\beta-\alpha}| \) is at the level of few times \( 10^{-3} \) or smaller. The gap

---

**FIG. 3.** \( |s_{\beta-\alpha}| \) versus reduced fermionic coupling \( C^F_F \) in type I (left) and \( C^H_U \) in type II (right). In the upper two panels, the color code shows the dependence on \( m_h \); in the lower two panels the dependence on \( m_A \), with points ordered from high to low \( m_h \) and \( m_A \) values, respectively. Note that the color scales for \( m_A \) are different for type I and type II because of the very different allowed ranges of \( m_A \).
between the red and the yellow/green/blue points is again caused by the CMS limits on $A \to Zh$. On the other hand, the opposite-sign region, $C_D^H \in [-1.1, -0.7]$, requires $s_{\beta-\alpha} \lesssim -0.04$ due to the fact that $s_{\beta-\alpha}$ and $\tan \beta$ are correlated in type II as illustrated in the right panel of Fig. 4. We see that $C_D^H = c_{\beta-\alpha} + s_{\beta-\alpha} \tan \beta \gtrsim 1$ for $s_{\beta-\alpha} \gtrsim 0$ but decreases below 1 when $s_{\beta-\alpha}$ turns negative. Consequently, for moderately negative $s_{\beta-\alpha}$ and large $\tan \beta$, the points are ordered from high to low $m_h$. In the right panel, we exhibit $s_{\beta-\alpha}$ vs $\tan \beta$ with the color code showing $C_D^H$ ordered from high to low values.

FIG. 4. In the left panel, we exhibit $|s_{\beta-\alpha}|$ versus $C_D^H$ in type II. The color code shows the dependence on $m_h$, with points ordered from high to low $m_h$ values. In the right panel, we exhibit $s_{\beta-\alpha}$ vs $\tan \beta$ with the color code showing $C_D^H$ ordered from high to low values.

FIG. 5. Fermionic couplings versus $\tan \beta$ in type I (upper panel) and type II (lower panels) with $|s_{\beta-\alpha}|$ color code. Points are ordered from high to low $|s_{\beta-\alpha}|$. 
enough $\tan \beta$, $C_D^H$ flips sign. Values of $|C_D^H| \lesssim 0.7$ are excluded by the fit of the signal strengths, but the opposite-sign solution with $C_D^H \approx -1$ is still phenomenologically viable. The region of $\tan \beta \gtrsim 50$ is excluded because of the strong constraints on $A \to \tau \tau$ decays from ATLAS [58] and CMS [59]; see also [49]. The $CP$-odd scalar mass $m_A$ does not have much influence, since it can only vary over the very limited range $420 - 630$ GeV in type II. Large deviations of $C_D^H$ may imply large excursions of the $H$ signal strengths away from 1, the details of which will be studied in Sec. III C.

The $\tan \beta$ dependence of the fermionic couplings, shown in Fig. 5, is also noteworthy. In both type I and type II, sizable deviations from $C_U^H = c_{\beta-\alpha} - s_{\beta-\alpha} / t_g = 1$ are possible only for small $\tan \beta$. In type II, $C_U^H$ very quickly converges to 1 once $\tan \beta \gtrsim 7$–8 because the allowed range of $s_{\beta-\alpha}$ decreases with increasing $\tan \beta$, as can be seen in the right panel of Fig. 4. In type I, the convergence of the fermionic couplings to their SM values is less pronounced due to the fact that, even for $\tan \beta = 60$, the full $|s_{\beta-\alpha}|$ range considered is allowed. For $C_D^H$ in type II, the situation is quite different, as this coupling is given by $\cos \alpha / \cos \beta$ instead of $\sin \alpha / \sin \beta$. For the normal-sign region, as soon as $\tan \beta$ is at least moderate in size ($\tan \beta \approx 10$), $C_D^H$ saturates the full range allowed by the measured signal strengths, even for small values of $|s_{\beta-\alpha}|$ of a few times $10^{-3}$. In contrast, as discussed in the previous paragraph, the opposite-sign solution is only possible for large enough negative $s_{\beta-\alpha}$, concretely $s_{\beta-\alpha} \lesssim -0.04$, cf. the right panel of Fig. 4. Overall, in these plots, the impact of the CMS limit on $A \to Zh$ is even more striking than in Fig. 3, as it excludes most points with $\tan \beta \approx 1.2$–1.8 in type I and the entire range of $\tan \beta \approx 1.5$–2 in type II. Note however that in both types, points with smaller $\tan \beta$ are not excluded. As will be detailed in the Appendix, these points have $m_A \gtrsim 400$ GeV and $m_h \lesssim 40$ GeV—a region not probed by the current CMS analysis.

Turning to the loop-induced Higgs couplings to gluons and to photons, we first note that the $H$ coupling to gluons, $C_{gH}$, is dominated by the top-quark loop, and its behavior is thus practically the same as that of $C_D^H$ in Figs. 3 and 5. We therefore do not show separate plots for $C_{gH}$. However, an
exception occurs for the opposite-sign $C^H_D$ solution, for which the $b$-loop contribution interferes constructively with the $t$-loop contribution, resulting in $C^H_D \approx 1.06$. (The same happens in the $m_h = 125$ GeV case; see [15,48]).

The coupling to photons, $C^H_\gamma$, is more complicated. Here, the main contributions come from $W$ and top-quark loops as in the SM, as well as from loops with charged Higgs bosons. The $W$ and top-quark loops contribute with

![Diagram](attachment:image.png)

FIG. 7. As for Fig. 6 but showing the dependence of $C^H_\gamma$ on $\tilde{m} \equiv \text{sgn} \tilde{m}^2 \sqrt{|\tilde{m}^2|}$. Points are ordered from high to low $\tilde{m}$.

![Diagram](attachment:image.png)

FIG. 8. Reduced triple Higgs coupling $C_{HHH}$ in type I (left) and type II (right), in the top panels with $m_h$ and in the bottom panels with $m_A$ color coding. Points are ordered from high to low $\tilde{m}$, $m_h$ or $m_A$ values.
opposite signs, and thus the values of $C_U^{\gamma} > 1$ ($C_U^{\gamma} < 1$) seen in Fig. 3 will lead to smaller (larger) $C_H^{\gamma}$, respectively. The $H^\pm$ loop typically also has the opposite sign relative to the $W^\pm$ loop and can thus substantially suppress $C_H^{\gamma}$ even at very small $\beta - \alpha$. (However, positive interference of the $W^\pm$ and $H^\pm$ loops is possible for low $m_{H^\pm}$, as noted at the end of Sec. II). The net effect on $C_H^{\gamma}$ is shown in Fig. 6. In particular, we observe a large variation in $C_H^{\gamma}$ in type I, where the charged Higgs boson can be light. For $|\beta - \alpha| \lesssim 10^{-2}$ and $m_{H^\pm} \gtrsim 500$ GeV, we find $C_H^{\gamma} \approx 0.95$ in both type...
I and type II, in agreement with the expected 5%–6% reduction of $C^H_T$ relative to the SM in the limit $|s_{\beta-\alpha}| \to 0$ with heavy $m_{H^\pm}$ [cf. Eq. (63)]. For $|s_{\beta-\alpha}| \gtrsim 10^{-2}$ (but still assuming that $m_{H^\pm}$ is large), this reduction can be more or less than 5% depending on the sign of $\bar{m}^2 \equiv 2m_{12}^2/\sin 2\beta$. Note however, that while $\bar{m}^2 < 0$ can reach values as large as $\sim -(350 \text{ GeV})^2$ $[-(200 \text{ GeV})^2]$ in type I [type II], respectively, $\bar{m}^2 > 0$ does not exceed $\sim (150 \text{ GeV})^2$. Therefore, in type II where $m_{H^\pm} > 480 \text{ GeV}$, $C^H_T$ is always below 1 (although one will need linear collider precision to pin this down with sufficient accuracy [62]). In contrast, in type I, for $m_{H^\pm} \lesssim 160 \text{ GeV}$ a value of $\bar{m}^2$ between about $(60 \text{ GeV})^2$ and $(120 \text{ GeV})^2$ can lead to a switch in sign of $g_{HHH}^T$, giving $C^H_T > 1$. The dependence on $\bar{m}^2$ is illustrated explicitly in Fig. 7. Of course such a light charged Higgs boson can also (and in fact more easily) suppress $C^H_T$, down to $C^H_T \approx 0.8$, irrespective of the value of $|s_{\beta-\alpha}|$.

Finally, we consider the trilinear $HHH$ coupling, which is useful for consistency checks of the model, provided it can be measured precisely enough. The dependence of $C_{HHH} \equiv g_{HHH}/g_{HHH}^{\text{SM}}$ on $|s_{\beta-\alpha}|$ and $m_h$ (top panels) as well as $m_A$ (bottom panels) is shown in Fig. 8. Similar to $C_{bhh}$ in the nondecoupling regime of the $m_h = 125 \text{ GeV}$ scenario [15], large values of the triple Higgs coupling beyond 1 can be achieved for $|s_{\beta-\alpha}|$ values of the order of 0.1 in the alignment regime of the $m_h = 125 \text{ GeV}$ scenario. But, there is no direct analogue to the decoupling regime of the $m_h = 125 \text{ GeV}$ scenario, where the triple Higgs coupling was always suppressed as compared to its SM prediction. Instead, in the $m_h = 125 \text{ GeV}$ scenario, $C_{HHH}$ can be enhanced or suppressed for any value of $m_A$. However, most of the points which might have had $C_{HHH} \gg 1$ are associated with $\tan \beta \approx 1–2$, which is precisely the range eliminated by the CMS limits on $gg \to A \to Zh$. In the end we are left with $C_{HHH} \approx 0.8–1.2$ in type I and $C_{HHH} \approx 0.9–1.02$ in type II.\footnote{Without the $gg \to A \to Zh$ limits, we find values up to $C_{HHH} \approx 1.4$, as discussed in the Appendix.} In type I, the possible variation is less important for smaller $m_A$, in particular for $m_A$ below about 100 GeV. Moreover, we note that $C_{HHH} \lesssim 1$ for $m_A \lesssim 60 \text{ GeV}$ in both type I and type II. Finally, the smallest values of $C_{HHH} < 1$ in type I are found for large $\tan \beta$, for...
while in type II $C_{HHH}$ converges to 1 with increasing $\tan \beta$, as shown in Fig. 9.

C. Signal strengths

The variations in the couplings to fermions discussed above have direct consequences for the signal strengths of the SM-like Higgs boson. In type I, the signal strengths in the $H \rightarrow \gamma\gamma$ decay mode are driven by the value of $m_{H^+}$, while for the $H \rightarrow VV$ ($VV = ZZ^*, WW^*$) and $H \rightarrow \tau\tau$ decay modes they depend mostly on $C_H^f$, as illustrated in Fig. 10.\(^\text{18}\) Notice that the $C_H^f$ dependence in the $ZZ^*$ mode is opposite for $gg$ fusion and vector boson fusion (VBF) production. In the case of VBF, a smaller value of $C_H^f$ implies a smaller $b\bar{b}$ partial width and therefore a larger $ZZ^*$ branching ratio, whereas in $gg$ production $C_H^f$ determines the size of the top-quark loop contribution which is enhanced for a larger value of $C_H^f$. In contrast, in type II, the

\(^{18}\)We employ the notation $\mu^X_H(Y)$ for the signal strength in the production mode $X$ and decay mode $H \rightarrow Y$. 
signal strengths are always dominantly driven by $C_H$, as this determines the $H \rightarrow b\bar{b}$ partial width (and $m_H$ is constrained to be heavy). This is illustrated in Fig. 11. In this case, the dependence is always the same for $gg$ and VBF production.

Putting everything together we find quite distinct correlations of signal strengths as shown in Fig. 12 for type I and in Fig. 13 for type II. It is especially noteworthy that even in the deep alignment limit, the signal strengths can significantly differ from the corresponding SM predictions, but the ratio of $gg$ and VBF production is very close to 1.

Moreover, certain combinations can only be reached for specific ranges of $m_h$ and/or $m_A$ values. For example, $\mu_H^{\gamma\gamma} \approx \mu_{VBF}^{\gamma\gamma} \approx 0.7$ requires $m_h \gtrsim 60$ GeV in type I while it is not reached at all in type II. Likewise, a suppression of $\mu_H^{\gamma\gamma}$ while $\mu_{VBF}^{\gamma\gamma} \gtrsim 1$ would point...
towards a somewhat heavy $A$ in type I with a slight departure from strict alignment, while again this combination is not possible in type II. Another example is the relation between $\mu_{Hgg}(\gamma\gamma)$ and $\mu_{Hgg}(ZZ/C3)$. In the alignment limit in type II we expect $\mu_{Hgg}(\gamma\gamma) = \mu_{Hgg}(ZZ/C3) \approx 0.9$, with both enhancement or suppression of the individual $\mu_{Hgg}(\gamma\gamma)$, $\mu_{Hgg}(ZZ)$ with respect to the SM being possible. In type I, there is a band in which this ratio also applies (for all $m_h$) and the signals are always suppressed. For values of $m_h \gtrsim 60$ GeV in type I, in the deep (near) alignment limit we find $\mu_{Hgg}(ZZ) \sim 1$ ($\in [0.95, 1.02]$), while $\mu_{Hgg}(\gamma\gamma)$ can range from 0.64 to 0.98 (1.4). An analogous discussion is possible for $\mu_{Hgg}(\tau\tau)$ versus $\mu_{Hgg}(\gamma\gamma)$.

In general, when $H \rightarrow hh$ or $H \rightarrow AA$ decays are kinematically allowed, these (so far) unobserved decay modes suppress the $H$ branching ratios into SM final states, thus leading to a simultaneous suppression of all the $\mu_X(Y)$ even in the deep alignment regime. This is apparent in all the $\mu$ correlations shown in Figs. 12 and 13, but is most notably visible as the upward-sloping diagonal lines of points in the $\mu_{Hgg}(ZZ)$ vs $\mu_{Hgg}(\gamma\gamma)$ and $\mu_{Hgg}(\tau\tau)$ vs $\mu_{Hgg}(\gamma\gamma)$ plots for type I. (However, note that in type II due to the nonuniversal nature of the Yukawa couplings the signal strengths can also be larger than 1 when the $H \rightarrow hh$ decay mode is open.)

Comparing these results with the corresponding results of [15], it seems very difficult to distinguish $m_H \approx 125$ GeV from $m_H \approx 125$ GeV with signal strength measurements and coupling fits alone. One possibility for such a distinction might be that the measured values point towards type I or type II but are excluded by $A \rightarrow Zh$ in the case of $m_H = 125$ GeV for a particular model type. Such a result would obviously favor the $m_h = 125$ GeV scenario.

**D. Cross sections for $h$ and $A$ production**

Let us now turn to the prospects for discovering the additional neutral scalar states. The two largest production
modes at the LHC are gluon fusion, $gg \rightarrow X$, and the associated production with a pair of $b$ quarks, $bbX$, with $X = h, A$. The correlations of the $gg \rightarrow X$ and $bbX$ cross sections at the 13 TeV LHC are shown in Fig. 14 for the type I model and in Fig. 15 for the type II model. We show the points that pass all present constraints (in beige) and highlight those that have a very SM-like 125 GeV Higgs state by constraining all the following signal strengths to be within 5% or 2% of their SM values, respectively, denoted as SM $\pm 5\%$ (red) and SM $\pm 2\%$ (dark red):
Regarding the production of $h$ and $A$ in type I, shown in Fig. 14, there is a strong correlation between the two production modes, gluon fusion and $b\bar{b}$ associated production, which stems from the fact that the relevant couplings are the same (up to a sign in the case of the $A$):

\[ \mu_{gg}(Y) = \mu_{gg}(ZZ^*) = \mu_{gg}(\tau\tau) = \mu_{VBF}(\tau\gamma), \]
\[ \mu^H_{VBF}(ZZ^*) = \mu^H_{VBF}(\tau\tau), \quad \mu^H_{VH}(b\bar{b}), \quad \mu^H_{t\bar{t}}(b\bar{b}) \].

(67)

The larger spread in $\sigma(b\bar{b}A)$ observed for $\sigma(gg \rightarrow A) > 10^{-2}$ pb comes from the fact that for $m_A \lesssim 400$ GeV the $b\bar{b}A$ cross section grows faster with decreasing $m_A$ than that of $gg \rightarrow A$. Therefore, along a line of fixed $\sigma(gg \rightarrow A)$ in the plot, a point with higher $\sigma(b\bar{b}A)$ has a smaller $m_A$. Note also that there is an interference of the top and bottom loop diagrams in $gg \rightarrow A$ which changes sign depending on the value of $m_A$. However, $\sigma(gg \rightarrow A)$ is always at least two orders of magnitude larger than $\sigma(b\bar{b}A)$.

Turning to type II scenarios, we observe that in the case of the $A$ either the $b\bar{b}A$ or the $gg \rightarrow A$ cross section can be dominant due to the fact that the $Ab\bar{b}$ and $At\bar{t}$ couplings have different $\tan\beta$ dependence, the former being proportional to $\tan\beta$ and the latter to $\cot\beta$. Also, as already noted in [49], the $m_H = 125$ GeV scenarios can be either eliminated or confirmed when the LHC measurements reach a precision such that the rates in the various initial × final state channels can be measured to 5% accuracy. This is because for this scenario the charged Higgs boson loop contribution to the $H\gamma\gamma$ coupling results in at least a 5% reduction in the $H\rightarrow \gamma\gamma$ coupling.

Before considering specific decay channels of $h$ and $A$, we present in Fig. 16 the gluon-fusion cross sections, as well as the $b\bar{b}A$ cross section, as functions of $m_h$ for $Y = \gamma\gamma$ (upper panels) and $Y = \tau\tau$ (lower panels) with $\tan\beta$ color code. Points are ordered from high to low $\tan\beta$.
scan are high enough such that a cancellation between the two terms of $C_F = s_{\beta-\alpha} + c_{\beta-\alpha} \cot \beta$ can occur and leads to an almost vanishing coupling. For $m_h < \frac{1}{2} m_H$, this cancellation is also possible for fine-tuned points at large $\tan \beta$, but for most points $\tan \beta$ is small and the cross section can be as large as $5 \times 10^3$ pb at $m_h \sim 10$ GeV. In type II, any phenomenologically viable mass in the range 420–630 GeV gives a $gg \to A$ cross section larger than 30 fb with values as large as 10 pb possible for $\tan \beta \lesssim 1$. Moreover, note that the $\tan \beta$ dependence is opposite for $b\bar{b}A$ compared to

FIG. 18. Cross sections times branching ratios in type I (left) and in type II (right) for $A \to Y$ signatures at the 13 TeV LHC as functions of $m_A$ with $Y = \gamma\gamma$ (upper panels), $Y = \tau\tau$ (middle panels) and $Y = t\bar{t}$ (lower panels) with $\tan \beta$ color code. Points are ordered from high to low $\tan \beta$. 
so that one or the other cross section is always large, as illustrated in the right panel of Fig. 15. As for h in type II, the smallest \( gg \to h \) cross section is of order 8 pb at \( m_h \approx 80 - 90 \) GeV at very large \( \tan \beta \). As previously mentioned, large values of \( \tan \beta \) are excluded for \( m_h < 80 \) GeV and \( m_h > 90 \) GeV because of the severe constraints from \( h \to \tau\tau \) decays. For values of \( m_h < \frac{1}{2} m_H \), for which \( \tan \beta \) must be small, the \( gg \to h \) cross section takes a minimum value of \( \sim 100 \) pb reaching \( 2 \times 10^3 \) pb at \( m_h \sim 10 \) GeV. To summarize, the prospects for observing the h look promising in both type I and type II.

Let us now turn to specific signatures.\(^{19}\) The cross sections for \( gg \to h \to Y \) with \( Y = \gamma\gamma \) and \( \tau\tau \) in types I and II are exhibited in Fig. 17. Note that the y axis is cut off at \( 10^{-7} \) pb. Although much lower values of the cross section are possible in some cases, we do not show these lower values since they will certainly not be observable at the LHC. In type II, \( gg \to h \to \gamma\gamma \) cross sections of at least 1 fb are guaranteed if \( m_h < \frac{1}{2} m_H \). In this same region one finds that \( \sigma(gg \to h \to \gamma\gamma) > 0.1 \) fb in type I if \( \tan \beta < 2 \). For \( m_h > \frac{1}{2} m_H \), cross sections in the \( \gamma\gamma \) final state can reach 10 fb (3 fb) in type I (type II), though they can also be much lower, especially in type I. The behavior of \( \sigma(gg \to h \to \tau\tau) \) is similar with cross sections above 1 pb over the full \( m_h \) range in type II, and also in type I if \( \tan \beta \) is small enough. Existing limits on \( \sigma(gg \to h \to \gamma\gamma) \) at 8 TeV from CMS for \( m_h = 80 - 110 \) GeV are roughly 0.05–0.1 pb at 68% C.L. [63]. Thus, we expect that future Run 2 data will eventually provide a sensitive probe in this channel, which will be particularly interesting if the analyses can be extended to cover the whole \( m_h \) range down to about 10 GeV.

The cross sections for A production with decays into SM channels, \( A \to \gamma\gamma, \tau\tau, t\bar{t} \), are presented in Fig. 18. In type I, the \( gg \to A \to \gamma\gamma (\tau\tau) \) cross section can be as large as roughly 15 fb (10 to 1 pb), respectively, for \( m_A \in [60, 200] \) GeV, with minimum values that would still be potentially observable for \( m_A \lesssim 100 \) GeV for a very large integrated luminosity.

\(^{19}\) To avoid a proliferation of plots, we focus here primarily on the results for gluon fusion; all corresponding results for the \( b\bar{b} \) cross section can be provided upon request.
BERNON, GUNION, HABER, JIANG, and KRAML PHYSICAL REVIEW D

For maximal value of $\beta$ the cross section is either zero or very tiny. Once $m_{A} > 2m_{t}$, a very substantial $gg \to A \to \bar{t}t$ cross section (up to about 0.3 pb for $\tan \beta > 2$ and roughly 0.1–6 pb for $\tan \beta < 2$) is possible for small $\tan \beta$, but as $\tan \beta$ increases this cross section declines rapidly. Turning to type II, we see that observation of the $A$ in the $\gamma \gamma$ final state will be, at best, extremely difficult. In contrast, observation of $b\bar{b}A$ production with $A \to \tau \tau$ may be possible at large $\tan \beta$. Moreover, $b\bar{b}A$ production is useful for observing the $A \to \bar{t}t$ decay in Type II. The cross section (not shown) ranges from 60–0.2 fb for $m_{A} \approx 420–630$ GeV, with only little dependence on $\tan \beta$. The cross section for $gg \to A \to \bar{t}t$ is sizeable (up to 8 pb) for very small $\tan \beta$, but below 0.1 pb for $\tan \beta \gtrsim 2$.

In evaluating the potential for the discovery of $A$ via the $\bar{t}t$ final state, it is noteworthy that $gg \to A \to \bar{t}t$ strongly interferes with the $pp \to t\bar{t}$ SM background, which yields a peak-dip structure in the $\bar{t}t$ invariant mass distribution [64–66]. One should also consider the set of complementary modes, $t\bar{A}$ associated production in types I and II, and $b\bar{b}A$ associated production in type II, followed (in both cases) by $A \to \bar{t}t$, as recently explored in [67–69].

While the sizable cross sections discussed above provide interesting probes of the extended Higgs sector in the alignment limit, the nonstandard signatures of $A \to Zh$ and/or $A \to ZH$ shown in Fig. 19 appear to be even more promising. 21 In Type II, there is a strict lower bound on the $gg \to A \to Zh$ cross section, with values above 1 pb at small $\tan \beta$ and at least of order 25 fb at large $\tan \beta$ even at the maximal value of $m_{A} = 630$ GeV. In Type I, at low $\tan \beta$ the $gg \to A \to Zh$ cross sections fall in the range $\sim 1$ pb to 20 pb while at large $\tan \beta$ this cross section could be as small as $\sim 0.1$ fb (or even smaller for $m_{A} < 220$ GeV). Given that the Run 1 searches in this channel remove a significant portion of the low $\tan \beta$2HDM type I and Type II points, it seems certain that Run 2 results would either be substantially more constraining or reveal a signal.

The cross sections for $gg \to A \to ZH$ are typically at least a factor of 100 smaller than those for the $Zh$ final state. Nevertheless, the $A \to ZH$ decay could provide an additional probe of the small-to-intermediate $\tan \beta$ regime, but will likely be unobservable at large $\tan \beta$ in both type I and type II.

A large $gg \to A \to ZH$ cross section could potentially have a substantial impact on the $\mu^{\mu}_{ZH}(\gamma)$ signal strength through the so-called “feed-down” effects [49,71], parametrized here by $\mu^{\mu}_{ZH} = \sigma_{A}(gg \to A \to ZH)/\sigma_{A}(q\bar{q} \to ZH)$. However, we observe that this effect is small in both types I and II, where $\mu^{\mu}_{ZH} < 0.16, 0.06$, respectively, for all points, implying that our global fit of the $H$ properties is not affected by the feed-down. This is due to the fact that the $A \to ZH$ coupling is proportional to $|\sin(\beta - \alpha)|$.

IV. CONCLUSIONS

In this paper, we studied the approach to the alignment limit of the 2HDM with type I and type II Yukawa couplings under the assumption that the observed Higgs boson with mass 125 GeV is the heavier $CP$-even scalar, $H$. With the $H$ mass eigenstate being approximately aligned with the direction of the scalar field vacuum expectation value in field space, its coupling to the $W$ and $Z$ bosons tends towards the SM value, $C_{H}^{W} \to 1$. Allowing for at most a 1% deviation from unity in $C_{H}^{W}$, we found that deviations in the couplings to fermions of 10%–20% are possible while maintaining consistency at 95% C.L. with the LHC Run 1 Higgs measurements. While $C_{H}^{W}$ in type I and $C_{H}^{W}$ in type II rather quickly approach unity as $|s_{\beta-\alpha}| \to 0$, the approach of the bottom Yukawa coupling to its SM value in the alignment limit is delayed in type II, with $C_{H}^{W} \approx 0.72–1.12$ even for values of $|s_{\beta-\alpha}| \sim 10^{-2}$. Moreover, there can be significant deviations from 1 in the loop-induced coupling to photons: $C_{\gamma} \approx 0.80–1.17 (0.88–0.97)$ in type I (II). In the case of Type I, the reason for the larger range of $C_{\gamma}$ and for its extending also to values above 1 is that the charged Higgs can be light. All these variations in the couplings feed into distinctive behaviors of the signal strengths. Thus, even in the deep alignment regime, where one might naively expect everything to be very SM-like, precise measurements of the signal strengths at 125 GeV can help determine the existence of the extended Higgs sector. Furthermore, correlations between signal strengths are characteristic for the model and can point towards a 2HDM of type I or type II.

Comparing with the results from [15], distinguishing $m_{h} \approx 125$ GeV from $m_{H} \approx 125$ GeV with signal strength measurements and coupling fits alone seems very difficult, unless one finds values that are excluded by $A \to Zh$ in the $m_{H} \approx 125$ GeV case. Preferably, and certainly more definitively, one would wish to observe the second $CP$-even scalar, $h$. Indeed, in the $m_{H} \approx 125$ GeV case studied in this paper, the $h$ must lie below 125 GeV by definition (which also implies that there is no decoupling limit for this type of model). Moreover, for $c_{\beta-\alpha} \gtrsim 0.99$, precision electroweak observables impose an upper limit on the masses of the $CP$-odd and the charged Higgs of $m_{A,H^{\pm}} \approx 630$ GeV, suggesting that all the extra Higgs states of the 2HDM are at least kinematically accessible at the LHC in this setup. While we did not study the potential for observing the $H^{\pm}$, direct detection of the $h$ and/or $A$ might be possible in a variety of production $\times$ decay channels. Most exciting and enticing is

---

20We thank Ning Chen and Tao Liu for bringing these studies to our attention.

21The LHC reach for $gg \to A \to Zh$ and $gg \to A \to ZH$ at $\sqrt{s} = 14$ TeV was previously investigated in [70].
the channel \(gg \rightarrow A \rightarrow Zh\) which would reveal the presence of both the \(h\) and \(A\) simultaneously. The associated cross section at \(\sqrt{s} = 13\) TeV is at least 20 fb (and can be as large as 10 pb) in type II. In type I, \(\sigma(gg \rightarrow A \rightarrow Zh)\) is also large, 10 fb to 30 pb, over most of the parameter space, although for very large \(\tan\beta\) it can drop below 1 fb in the ranges \(m_A \approx 90–250\) GeV and \(m_A \gtrsim 500\) GeV. The searches for \(A \rightarrow Zh\) with \(Z \rightarrow \ell\ell\) and \(h \rightarrow b\bar{b}\) or \(\tau\tau\) are therefore excellent probes for discovering or excluding the 2HDM scenarios with a SM-like \(H\), provided that they are performed without requiring a SM-like \(h\) with \(m_h = 125\) GeV. In fact, CMS has already performed such a search for \(A \rightarrow Zh\) at \(\sqrt{s} = 8\) TeV for general \(m_A\) and \(m_h\) values (down to 40 GeV), and the limits they obtained are among the most severe constraints for the scenario studied in this paper.

Other channels of high interest include \(gg \rightarrow h \rightarrow \gamma\gamma\) (for \(m_h \lesssim 90\) GeV) as well as \(gg \rightarrow h \rightarrow \tau\tau\) (or \(\mu\mu\)) in type II. The \(\gamma\gamma\) channel may also reveal a light \(A\) in type I if \(\tan\beta\) is small. Moreover, \(gg \rightarrow A \rightarrow \tau\tau\) (or \(\mu\mu\)) can be used to search for a light \(A\) in the 10–250 GeV mass range in type I, while in type II it would be preferable to exploit the \(b\bar{b}A\) production mode to search for the same \(A\) decays (over the relevant mass range of \(m_A \approx 420–630\) GeV). Finally the \(t\bar{t}\) final state can be relevant for \(m_A\) above 350 GeV in both type I and type II if \(\tan\beta\) is small.

In short, it is possible that the observed 125 GeV Higgs boson appears SM-like due to the alignment limit of a multidoublet Higgs sector. However, the alignment limit does not necessarily imply that the additional Higgs states of the model are heavy. Indeed, it is possible that the observed Higgs boson at 125 GeV is the heavier \(CP\)-even \(H\), in which case \(m_h \in [10, 121.5]\) GeV (since we intentionally avoided the case of \(h\)–\(H\) mass degeneracy) and \(m_{A, H} < 630\) GeV. Such a scenario, if realized in Nature, would lead to exciting new effects to be probed at Run 2 of the LHC.

H. and S. K. are grateful for the hospitality and the inspiring working atmosphere of the Aspen Center for Physics, supported by the National Science Foundation Grant No. PHY-1066293, where this project was initiated.

**APPENDIX: IMPACT OF THE CMS \(A \rightarrow Zh\) EXCLUSION**

Both ATLAS and CMS have performed searches at \(\sqrt{s} = 8\) TeV for a new heavy resonance decaying to a \(Z\)
boson and a light resonance, with the $Z$ decaying to $\ell\ell = ee, \mu\mu$ and the light resonance decaying to $b\bar{b}$ or $\tau\tau$. While the ATLAS analysis\,[55] required that the light resonance be consistent with the observed 125 GeV Higgs boson, the CMS analysis\,[17] treated the masses of the two resonances as free parameters and published limits on cross section times branching ratios as functions of the two masses. We can therefore use this CMS result as a constraint on $A \rightarrow Zh$ in our study.

For values of $m_A \approx 200–600$ GeV, which is the mass range of particular interest for our analysis, the 95% C.L. limit on $\sigma(gg \rightarrow A \rightarrow Zh) \times \text{BR}(Z \rightarrow \ell\ell) \times \text{BR}(h \rightarrow b\bar{b})$ obtained by CMS is about 100 fb for $m_h \approx 40–45$ GeV, corresponding to the lowest $m_h$ considered in [17]. For heavier $m_h$, the limit is about 100 fb at $m_A \approx 200$ GeV going down to about 5 fb at $m_A \approx 600$ GeV. As previously mentioned, this is a very severe constraint for the 2HDM in the alignment limit with $m_H = 125$ GeV, cutting out whole slices of parameter space, in particular at low $\tan\beta$. The limit on $\sigma(gg \rightarrow A \rightarrow Zh) \times \text{BR}(Z \rightarrow \ell\ell) \times \text{BR}(h \rightarrow b\bar{b})$ has a weaker impact. Indeed, most of the points excluded by the $\ell\ell\tau\tau$ search channel are also excluded by the $\ell\ell b\bar{b}$ channel. Nonetheless, in type I there is a small corner of parameter space at $\tan\beta \approx 2$ and $m_A \lesssim 400$ GeV that is mostly constrained by the $A \rightarrow Zh \rightarrow \ell\ell\tau\tau$ CMS limit. The impact of the CMS $A \rightarrow Zh$ exclusion is illustrated explicitly in Figs. 20–27.

In Fig. 20 we show the projections of the scan points onto the plane $\tan\beta$ versus $m_A$ for both type I and type II. The red points are consistent with all constraints used in this paper, while the underlying black points are those which are excluded by the CMS $A \rightarrow Zh$ ($Z \rightarrow \ell\ell$, $h \rightarrow b\bar{b}$, $\tau\tau$) limits\,[17] after all other constraints have been applied. We see that the $A \rightarrow Zh$ limit from Run 1 excludes a whole slice of parameter space at low $\tan\beta$ and $m_A$ above about 300 GeV. The surviving red points with $m_A > 400$ GeV and $\tan\beta < 2$ have $m_h \lesssim 40$ GeV. Had the CMS analysis been sensitive to light resonance masses below 40 GeV, the entire parameter space with $m_A > 400$ GeV and $\tan\beta < 2$ would have been ruled out.

The effect on the allowed ranges of the reduced couplings is shown in Figs. 21–24. These plots can be directly compared to the ones in Sec. III B. Particularly striking is the impact on $C_{\gamma}^H$ in type II, where the previously possible deviations below the canonical value of $C_{\gamma}^H \approx 0.95$ are now largely ruled out. Likewise, large deviations of $C_{HHH} > 1$ are
FIG. 23. As in Fig. 20 but in the plane $|s_{\beta-\alpha}|$ vs $C_y^H$. To be compared to Fig. 6.

FIG. 24. As in Fig. 20 but in the plane $|s_{\beta-\alpha}|$ vs $C_{HHH}$. To be compared to Fig. 8.

FIG. 25. As in Fig. 20 but in the plane $\mu_{\gamma\gamma}^H$ vs $\mu_{\gamma\gamma}^{H_{bb}}$ in type I (left panel) and $\mu_{\gamma\gamma}^{H_{bb}}$ vs $\mu_{\gamma\gamma}^{H_{bb}}$ in type II (right panel) planes. To be compared to the fourth and first rows of Fig. 12 and Fig. 13 respectively.
very much restricted by the $A \to Zh$ limit in both type I and type II, as shown in Fig. 24. Examples for the impact on the signal strength correlations in type I and type II are shown in Fig. 25.

Finally, we examine the impact of the CMS data for $A \to Zh$ on the cross sections for the production of $A$ and $h$. Significant parts of the parameter space are eliminated, as exemplified in Figs. 26 and 27.
